A partial earth signifies some weak spot in the insulation covering where the covering is partially worn away, due to corrosive action, abrasion, or mechanical damage of any kind. A partial earth may also be caused by "wet rot." This condition of the insulation is usually brought about by damp state of the atmosphere or walls, or dripping water, action of steam, etc. The insulation then becomes softened and "soddened," and when the two cables get touching, or close together, the leakage current becomes abnormally great; and with wet casing, electric sparks will flash intermittently across the path. This leakage and minute "arcing" will eventually overheat the insulation and casing, which will probably burst into flame.

A dead earth is obtained when there is actual metallic connection between either of the mains and "earth"; by "earth" is signified any system of water or gas pipes, or any such unconfined conducting or semi-conducting medium that would allow the current to leak away; it also means the actual soil. Of course, when there is a dead earth on both mains, a short-circuit is produced, for the current will enter earth by one main and leave by the other.

A rough test for earths is shown in Diagram I. of Fig. 42. G and B signify a linesman's galvanometer and battery, one pole or wire of which is put to earth, and the other is joined on to one of the mains, which is disconnected from the other main by the removal of all lamps; then, if there should happen to be an earth on the main to which the galvanometer is connected, the needle will show a greater or less deflection, because the circuit will be completed. In a similar way, an earth or fault can be detected in the other main by joining up the galvanometer to that main. This simple test does not give any quantitative information respecting the fault: it only shows in a rough way that a fault is extant.

To obtain a quantitative test, or measure the insulation resistance of the circuit, some such testing set like the "Silvertown" one must be used. This set is, perhaps, the best there is for rough practical use, such as in central-station work, and it is particularly handy for this sort of work. It is described and illustrated in several books on electric appliances, and those who do not know it can find it in Jamieson and Munro's pocket-book. The method of using this set is as follows: Insert the two battery wires into the two terminal holes marked "insulation," and having first adjusted the needle of the galvanometer to zero by means of the controlling magnet, then plug up the hole marked "10,000 ohms," and observe what deflection is given and what shunt is used. The best combination of battery power and shunts to be used must be guided by the probable value of the insulation resistance, because to obtain the best results the deflection obtained from the insulation resistance must be made to coincide as near as possible with that obtained from the 10,000 ohms. In addition, it is always best to obtain a deflection as near as possible to 45deg. When this operation has been done, one of the mains of the circuit about to be tested is connected up to the screw terminal marked "insulation," placed on the left-hand side of the galvanometer. A wire is then attached to the right-hand screw terminal, marked "earth," and its other end is fixed on to a gas or water pipe, to make a good earth. To get a bright and clean contact, always scrape away the surface or skin of the pipe, as the test depends on having a good "earth." All that now remains to be done is to connect up the battery wires as before and plug up the hole marked "insulation," which is next to the 10,000-ohm hole. Note the new deflection and the shunt, if any shunt be used.

There are thus three variables in use: first, the number of cells; second, the shunt used; third, the value of the deflections.

With cells and shunt constant, $R_i \propto$ inversely as deflection.
With cells and deflection ,, $R_i \propto$,, ,, shunt.
With shunt and deflection ,, $R_i \propto$ directly as cells.

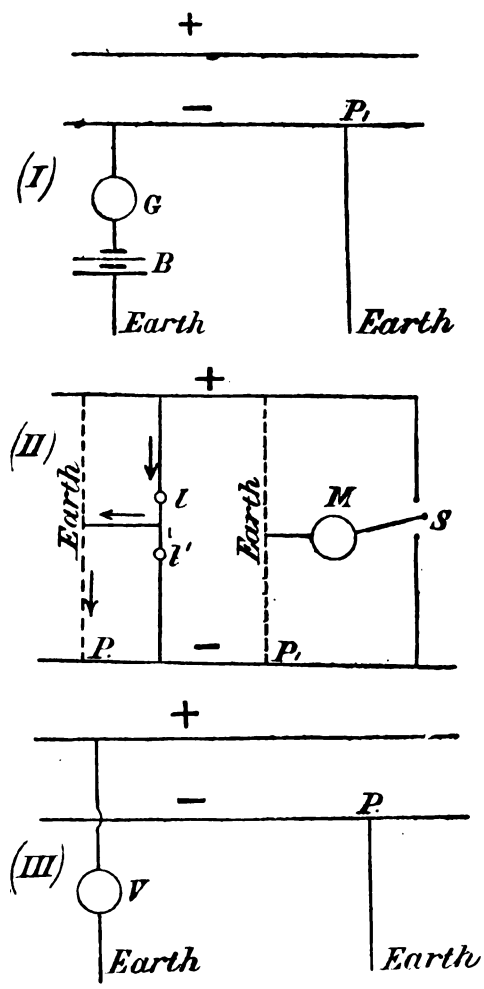

FIG. 42.

The above statements can easily be reasoned out, R_i signifying insulation resistance as compared to the standard resistance of 10,000 ohms. These can be expressed in the following formula:

$$R_i = \frac{D_1}{D_2} \times \frac{S_1}{S_2} \times \frac{N_2}{N_1} \times 10{,}000,$$

where D_1, S_1, and N_1, refer to the deflection, shunt, and number of cells when using the 10,000-ohm plug, and D_2, S_2, and N_2, the same when using the insulation-resistance plug.

When using the 10,000 ohms, it is usual to obtain what is termed a constant. This is obtained by multiplying the 10,000 ohms by the deflection, then by the value of the shunt, and then dividing by the number of cells used. Putting K for constant, this gives us

$$K = \frac{10{,}000 \times S_1 \times D_1}{N_1}.$$

Digitized by Google

When this constant is found, the formula for the insulation resistance becomes

$$R_i = \frac{K N_2}{D_2 S_2}.$$

The writer appends the results he obtained when using this testing set a short time ago, the deflections being for various numbers of cells and various shunts. With the 10,000 ohms in circuit these deflections vary slightly with the condition of the cells, etc., so they must not be taken as anything fixed. The last column gives the constant, K, calculated out. The two shunt plugs are marked $\frac{1}{9}$ and $\frac{1}{99}$; this signifies that when the $\frac{1}{9}$ plug is inserted, the multiplying power of the shunt is 10—that is to say, that only one-tenth of the total current passes through the galvanometer, the remaining nine-tenths passing by. Similarly, when the $\frac{1}{99}$ plug is in, the multiplying power of the shunt is 100.

TABULATION 33.

Deflection $= D_1$.	Shunt $= S_1$.	Cells $= N_1$.	Constant $= K = \frac{D_1 \times S_1 \times 10{,}000}{N_1}$.
42	10	10	420,000
4	100	10	400,000
Too high	10	20	—
8	100	20	400,000
Too high	10	30	—
11	100	30	366,666
Too high	10	40	—
15	100	40	375,000
Too high	10	50	—
18	100	50	360,000
Too high	10	60	—
23	100	60	383,333

The average value for K is 386,000.

These constants ought, of course, to all come out the same value. Their variation, however, is accounted for by different degrees of sensitiveness for various deflections, inequalities of cells, etc.

Diagram II. of Fig. 42 illustrates a very good way of obtaining a continual indication respecting the state of the insulation resistance. Two lamps of 16 c.p., l and l_1, are connected in series across the mains, and the wire connecting them in series is led to earth. The brilliancy of the lamps indicate the state of the insulation resistance of the circuit. In central stations the lamps can be connected to the two omnibus bars where a low-pressure parallel system is used. Suppose some part of the – conductor makes an earth somewhere, as shown at P, then a flow of current will take place from the + conductor through lamp l to earth, and thence to the – conductor, as shown by the arrows; consequently, the lamp will glow more or less brilliantly according to the quantity of current flowing through it, and this will depend upon the resistance there is between the earth and the – conductor. The same thing occurs when the + conductor has an earth on it; then, however, the lamp l_1 will glow instead of the lamp l, so that the brilliancy of that lamp connected to *one* conductor will indicate the state of the insulation of the *other* conductor.

When both lamps glow equally, then the insulation resistance of each conductor is equal. The lamp, however, only gives a rough test, and in order to obtain some measurement of the leakage current, it is necessary to employ a low-reading ammeter. This method is shown in Diagram II. also; for in place of the two lamps the ammeter, M, is placed, having a switch, S, so that either the + or the – side of the circuit can be connected up. Let the ammeter be joined on to the + side, and suppose it shows a current of ·8 of an ampere. This means an earth on the – side, shown by dotted lines between P_1 and earth, which thus allows a small current to flow from the + to the – side; and, since it is assumed that the resistance to this leakage current is between earth and the – side, hence it measures the insulation resistance of the – side; the resistance of the ammeter being extremely small, it may be neglected. Applying Ohm's law, this insulation resistance is obtained by dividing the pressure of the circuit by the leakage current. Suppose the circuit pressure is 110 volts, the leakage to earth on the – side is ·8 of an ampere, then the insulation resistance of the – side will be $110 \div \cdot 8 = 137$ ohms. For this test very low-reading ammeters are required, ranging from 0 to, say, six or seven amperes, with readings of one-tenth of an ampere, and these are not met with in central stations. The following test, however, is one that can always be made. It consists in simply supplanting the ammeter by a voltmeter, the only thing that is necessary to be known being the resistance of the voltmeter.

Diagram III. illustrates the connections. If there is an earth on the – side there is a deflection of the voltmeter when joined up to the + side, the result of a small current flowing from the + side through the voltmeter, and then along the dotted path between earth and the – side. The total resistance between + and – side consists of the resistance of the voltmeter and the resistance between earth and the – side, this latter forming the insulation resistance of the – side.

Let r = voltmeter resistance;
R_i = insulation resistance;
E = pressure of the circuit in volts;
D_1 = deflection of voltmeter across mains;
D_2 = deflection of voltmeter across mains when earthed.

The deflection obtained will be inversely proportional to the total resistance.

Hence $$\frac{D_1}{D_2} = \frac{R_i + r}{r};$$

but $D_1 = E$ because it indicates numerically the voltage of the circuit. Therefore, supplanting D_1 by E, we have

$$\frac{E}{D_2} = \frac{R_i + r}{r}; \quad \therefore R_i = \frac{E r}{D_2} - r.$$

Taking a practical case, let the pressure of the circuit be, say, 110 volts, the resistance of the voltmeter 2,000 ohms, and suppose we obtain a deflection of 12deg. when connected between the + omnibus bar and earth; then

$$R_i = \frac{110 + 2{,}000}{12} - 2{,}000 = 16{,}333 \text{ ohms};$$

so that in this case the insulation resistance of the whole of the – side of the circuit comes out to 16,333 ohms.

(To be continued.)

ON THE DESIGN OF ELECTROMAGNETS FOR SPECIFIC DUTY.*

BY E. R. CARICHOFF.

Exigencies demanding the design of an electromagnet to perform a specific duty where maximum efficiency was necessary, and no experimenting permitted, the writer made some preliminary calculations, and found that with certain conditions the best results were obtained by reducing the polar area, and with other conditions the best results were obtained by increasing the polar area. After going through the excellent work of S. P. Thompson on the electromagnet, and not finding there or elsewhere any formulated statements showing the proper relation that should exist between the magnetic reluctance of the air-gap and the iron of the magnet, the writer tabulated a lot of results, and finally hit upon the following easy method of determining the relative air-gap and iron reluctance in order to get the maximum work out of a given magnet, where work equals initial pull times travel.

The writer offers this with the belief that it is entirely original, although it seems strange that so simple a relation has never been pointed out before.

To explain the method, let us assume, for example, that the curve in Fig. 1, O E C D, represents our iron, and O F our air-gap characteristic, and that we are working at the point C on said curve. Reduce the polar area A by d A, and suppose that the force is reduced for an instant by $d\mathfrak{F}$, so that the induction in the air-gap is still $\mathfrak{B}$, and that in the iron is reduced by $\Delta\mathfrak{B}$. Since a tangent drawn to the curve at C is parallel to the line O F, we see that the force

* From the *Electrical World* (New York).

Digitized by Google

necessary to produce a change $\Delta \mathfrak{B}$ in the induction is the same in both iron and air-gap. Therefore, if $d\mathfrak{F}$ produces in iron a change $\Delta \mathfrak{B}$, it can produce $^1/_2 \Delta \mathfrak{B}$, say $d\mathfrak{B}$ in both.

It is evident that with the above assumptions

$$\frac{\Delta \mathfrak{B}}{\mathfrak{B}} = \frac{d\,A}{A} \text{ and } d\mathfrak{B} = {}^1/_2\,\mathfrak{B}\,\frac{d\,A}{A}.$$

With area A and induction $\mathfrak{B}$ the pull is proportional to $\mathfrak{B}^2$ A.

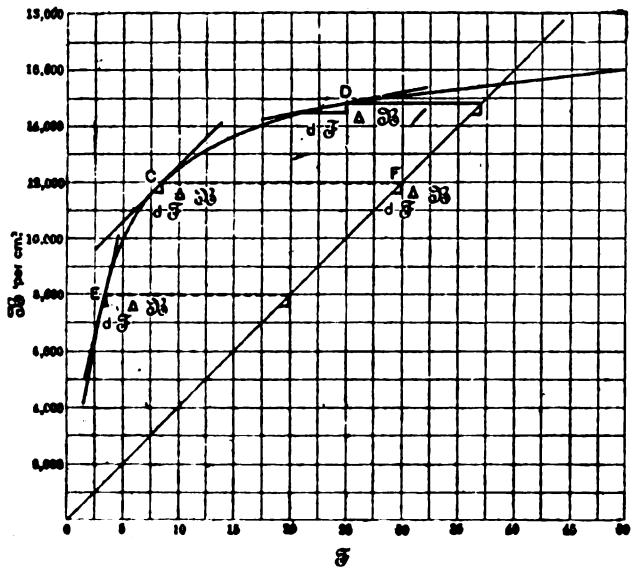

FIG. 1.

With the area $(A - d\,A)$ and the induction $\mathfrak{B} + d\mathfrak{B}$, we have $(\mathfrak{B} + d\mathfrak{B})^2 (A - d\,A)$ proportional to pull.

Then

$$\mathfrak{B}^2 A <=> (\mathfrak{B} + d\mathfrak{B})^2 (A - d\,A) \quad . \quad (1)$$

if $^1/_2\,\mathfrak{B}\,\frac{d\,A}{A} <=> d\mathfrak{B}$.

Since for this case $d\mathfrak{B} = {}^1/_2\,\mathfrak{B}\,\frac{d\,A}{A}$, the two sides of the equation are the same and the pull is the same when the polar area is A and when it is $A - d\,A$. In the same way it can be shown that the pull is the same where the polar area is A and $A + d\,A$.

From this we draw the conclusion that when the air-gap reluctance is expressed by a line parallel to the tangent drawn at the part of the iron characteristic where we are working, there is no gain by either increasing or decreasing the polar area. This is evidently the condition of maximum efficiency, as we shall see from further considerations.

Keep the same characteristics and suppose our ampere-turns put us at the point D on the iron curve. Decrease the polar area by $d\,A$, and for an instant the force by $d\mathfrak{F}$, so that $\mathfrak{B}$ is still the induction in the air-gap. $d\mathfrak{F}$ is now much greater than before necessary to make the change $\Delta \mathfrak{B}$, so that it will produce a change in the whole circuit by an amount, $d\mathfrak{B}$, referred to air-gap, where $d\mathfrak{B}$ is greater than $^1/_2 \Delta \mathfrak{B}$, or greater than $^1/_2\,\mathfrak{B}\,\frac{d\,A}{A}$. This condition makes the right-hand member of equation (1) greater than the left-hand member, showing that the pull is increased by decreasing the polar area. Increase the polar area by $d\,A$, keeping other conditions as above, and equation (1) shows that the pull is decreased. Therefore, if our iron curve shows that $\frac{\Delta \mathfrak{B}}{d\mathfrak{F}}$ is greater than the same function for the air-gap, the air-gap reluctance should be increased until the two functions are the same.

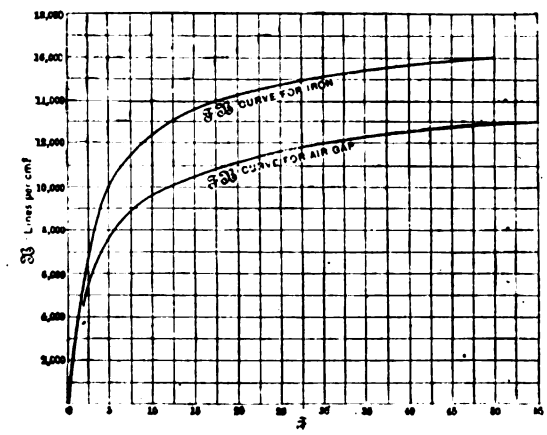
Again, at the point E we find that $d\mathfrak{F}$ is less than in the case first cited, and if the same reasoning is followed it is found that the pull is increased by increasing the polar area.

Instead of increasing or decreasing the polar area, the same results are gotten by shortening or lengthening the air-gap. When this is done, so that the function $\frac{\Delta \mathfrak{B}}{d\mathfrak{F}}$ is the same for iron and air-gap, the pull multiplied by the distance is a maximum. This being the case, the best results are obtained by using the proper air-gap; and if this distance is not the travel required, a lever can be used to multiply or divide with.

With these principles in view, it is easy to get the most efficient possible arrangement. It is also easy to predetermine a magnet to pull required amounts in more than one point of its travel.

By drawing tangents to all points of the iron curve, and lines from the original parallel to these tangents, and intersecting these by horizontal lines, we get the curve of proper air-gap for all points of iron curve cut by said horizontal lines. See Fig. 2.

There are some other curves that materially reduce the labour in designing an electromagnet for a definite work.



$\frac{\Delta \mathfrak{B}}{\Delta \mathfrak{F}}$ CURVE FOR IRON
$\frac{\Delta \mathfrak{B}}{\Delta \mathfrak{F}}$ CURVE FOR AIR GAP
$\mathfrak{B}$ Lines per cm²
$\mathfrak{F}$

FIG. 2.

To prove that the air-gap thus determined gives the maximum amount of work, which work equals initial pull times length of gap, change l by $d\,l$; then

$$\frac{\Delta \mathfrak{B}}{\mathfrak{B}} = \frac{d\,l}{l}.$$

We see that for the point F

$$\frac{d\mathfrak{F}}{\Delta \mathfrak{B}} = \frac{d\mathfrak{F}}{\Delta \mathfrak{B}},$$

and $$d\mathfrak{B} = \mathfrak{B}\,{}^1/_2 \Delta \mathfrak{B},$$

and for points to the right of F,

$$d\mathfrak{B} > {}^1/_2 \Delta \mathfrak{B},$$

and for points to left of F,

$$d\mathfrak{B} < {}^1/_2 \Delta \mathfrak{B}.$$

In the three cases the work will be proportional respectively to

$$\mathfrak{B}^2 l \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$
$$(\mathfrak{B} - d\mathfrak{B})^2 (l + d\,l) \quad . \quad . \quad . \quad . \quad (2)$$
$$(\mathfrak{B} + d\mathfrak{B})^2 (l - d\,l) \quad . \quad . \quad . \quad . \quad (3)$$

$$(1) - (2) = + \text{ for } d\mathfrak{B} > {}^1/_2\,\mathfrak{B}\,\frac{d\,l}{l};$$

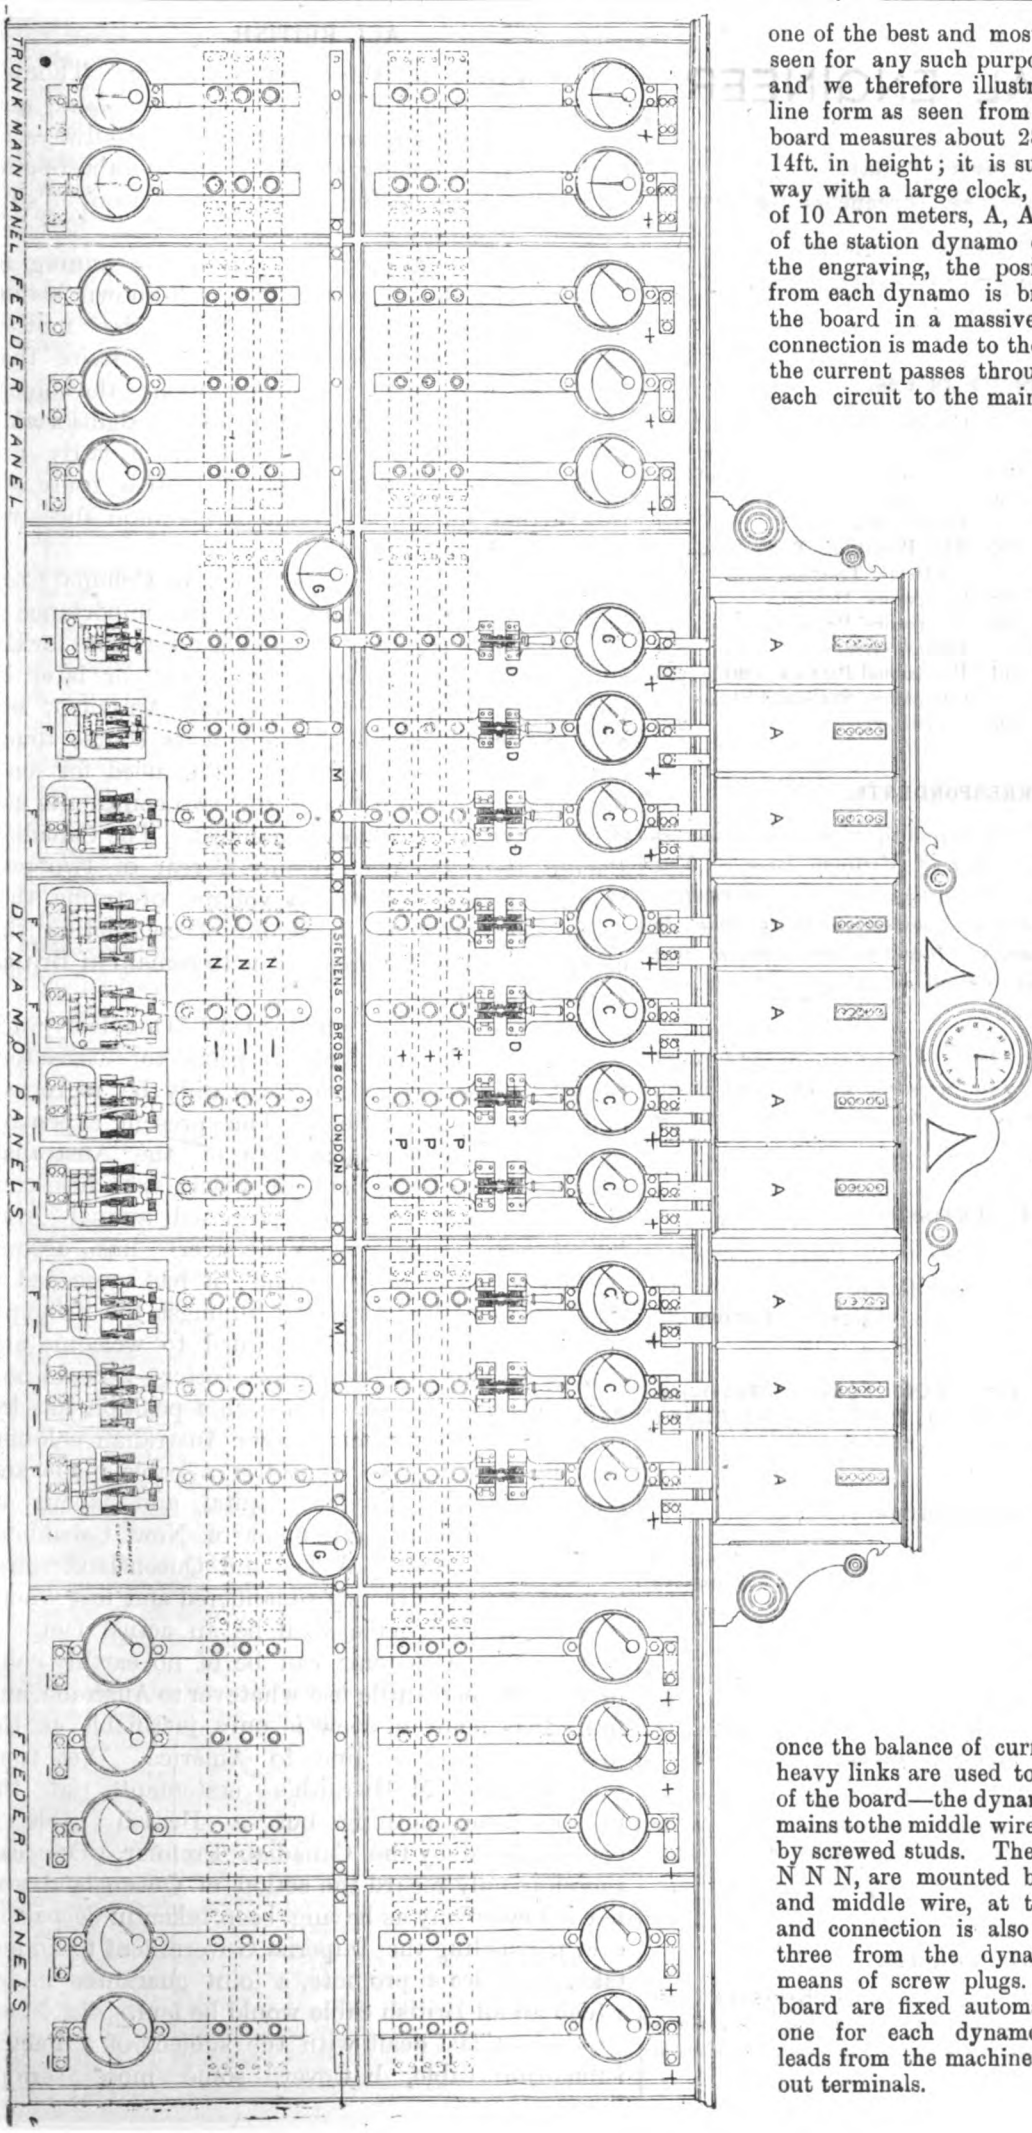
$$(1) - (3) = + \text{ for } d\mathfrak{B} < {}^1/_2\,\mathfrak{B}\,\frac{d\,l}{d\,l}.$$

NEW MAIN SWITCHBOARD—CARNABY STREET STATION.

Everyone knows that the St. James' and Pall Mall Electric Light Company is looked upon as obtaining the very cream of electric lighting work, the district served being small, yet requiring a great number of lights almost constantly in use. Of course this led to the adoption, and very successful use, of a continuous-current low-voltage system of supply, though in order to save expense upon street mains the three-wire arrangement of distribution is in force.

At the Carnaby-street station of this company, Messrs. Siemens Bros. and Co., Limited, are now engaged in erecting a large new main switchboard from their own design and workshops, which appears to be

Digitized by Google



New Main Switchboard—Carnaby-street Station, St. James' and Pall Mall Electric Light Company, Limited.

one of the best and most compact we have yet seen for any such purpose as that in question, and we therefore illustrate it herewith in outline form as seen from the front. The entire board measures about 28ft. in length by nearly 14ft. in height; it is surmounted in the usual way with a large clock, beneath which is a row of 10 Aron meters, A, A, A, etc.—one for each of the station dynamo circuits. As shown in the engraving, the positive main, marked +, from each dynamo is brought to the front of the board in a massive terminal, from which connection is made to the meter above. Thence the current passes through an ammeter, C, for each circuit to the main switch, D, thence to a solid bar pierced with three holes, through any of which a large contact plug may be screwed into three positive omnibus bars at the back of the board, shown by the dotted lines in the illustration, and marked P. From these the current is taken as required to any of the feeder circuits by similarly coupling them up with screw plugs, or it may pass into the trunk mains connecting this station with that at Duke-street—also belonging to the St. James' and Pall Mall Company—either station thereby helping the other. Ammeters are provided for these circuits — feeder or trunk main—on both positive and negative sides. It will be noticed, however, that those on the trunk circuits are marked with their zero point in the centre of the scale, so that they show not only the amount of current passing, but also whether it is entering the station or leaving it, according as the ammeter needle is on one side or the other of zero. A similar type of ammeter is used on the middle or neutral bar, M, of the three-wire system, as shown at G. The engineer can see at once the balance of current either way. Short heavy links are used to connect—on the front of the board—the dynamo positive and negative mains to the middle wire, being fastened securely by screwed studs. The negative omnibus bars, N N N, are mounted below the positive bars and middle wire, at the back of the board, and connection is also made with any of the three from the dynamo negative bars by means of screw plugs. At the base of the board are fixed automatic cut-outs, F, F, etc., one for each dynamo circuit, the negative leads from the machines coming up to the cut-out terminals.

ALL BRITISH.

The arrival in this country of Sir Thomas McIlwraith, the late Premier of Queensland, and now Chief Secretary and Secretary for Railways in that important colony, affords us a favourable opportunity of again dealing with the question of submarine telegraphic intercommunication between Canada and Australia; of incidentally joining in the cordial welcome which this well-known statesman will doubtless receive from the mother country, and of expressing a fervent desire that his visit may help to bring about the object of which every right-minded and straightforward Englishman will approve when it is fairly put before him—viz., that of an all-British route for this further link in the bond of common ancestry, speech, and civilisation.

Six years have now passed since the Colonial Conference emphasised unanimously the importance of using not only the shortest and cheapest route for the submarine cable (which must sooner or later be put down between Australia and America), but also one which should throughout its course touch nowhere but on British soil. The need for such further intercourse between the two continents had even at that date become manifest. The Canadian Pacific Railway—opened only a year or two previously—already showed a volume of traffic that spoke very strongly in favour of completing the connection in such a manner as to remain in British hands throughout.

Since then, what has happened? One delay after another has led in some respects to satisfactory results; in others to what can only be regretted, and amended if possible. The present expensive monopoly (under which five of the Australian colonies alone have paid in yearly subsidies considerably more than the proposed annual grant for a new cable *viâ* Vancouver) has accomplished at least one good end: it has succeeded in creating such dissatisfaction amongst the principal colonists that they feel inclined to welcome any change as being likely to prove better—it could not, apparently, be worse. But such a position has led to the regrettable fact of two Australian colonies actually agreeing to subsidise a cable made and laid wholly by French capital and labour as far as the French settlement of New Caledonia. Surely New South Wales and Queensland must look upon this as money squandered and lost whenever the through cable shall be an actual fact. A line to New Caledonia can be of no earthly commercial or mercantile use whatever to Australia, and from that point of view is only justifiable as the first portion of a line to America. Yet from Sir Thomas McIlwraith's statements, at the present time nothing but a British cable is contemplated by the Canadian Premier. One can therefore only regard the action of Queensland and her fellow-colony as having been taken in despair of ever persuading the Imperial Government to undertake, or at least promote, a joint guarantee under which an all-British cable would be laid.

Since we last dealt with the subject of a Pacific submarine cable, however, some more serious

Digitized by Google

attempts have been made to arouse concerted action; and foremost amongst those who have exerted themselves in the matter has been Mr. Sandford Fleming, C.E., formerly engineer to the Canadian Pacific Railway. Mr. Fleming has spent many months in the Australian colonies, bringing the question in every detail before the responsible heads of government; a similar visit has been paid by Mr. Bowell, the Canadian Minister of Trade and Commerce; and whilst thus endeavouring to arrange for united action at one end of the line, they have not forgotten to set the matter clearly before the Imperial Government at the other end.

As a result of their efforts, it is pleasing to hear that in June next an inter-colonial conference will be held at Ottawa for the express purpose of considering the whole question, and, if possible, of arriving at some definite and unanimous conclusion. If their present frame of mind should continue (Sir Thomas McIlwraith, for instance, has expressly declared that the Queensland Government declines to be a party to the monopoly of the Eastern Extension Telegraph Company, and aims at a policy of free hand, even to the extent of subsidising a second cable), the Australian colonial Governments, aided by the cordial goodwill and hearty approval of Canadian statesmen, may safely be relied upon to arrive at so definite and clearly defined a position in the matter that the Imperial Government will find itself absolutely compelled not merely to approve of the proposed step, but to support it in such a manner as to secure its success at no very remote period.

CORRESPONDENCE.

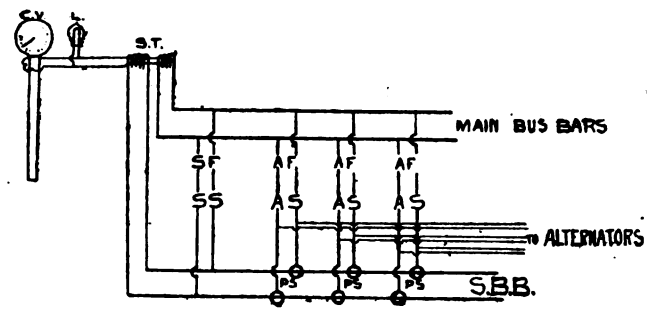
"One man's word is no man's word,
Justice needs that both be heard."

THE RUNNING OF ALTERNATORS IN PARALLEL.

SIR,—As there still appears to be a want of more general knowledge as to the facility with which alternators may be run in parallel, a few remarks as to such running at this station may be of interest to your readers, and serve to correct the erroneous impression that would be received from the remarks of "A Member" of the Northern Society of Electrical Engineers, as published in the report of their recent meeting.

Whenever more than one alternator is running on the mains of this station, they of necessity run in parallel. During the past winter, alternators have been put in parallel on an average of nine times per week. There has never been any difficulty in running, and there is no danger of an accident due to large synchronising currents in switching in parallel in the ordinary way if due care is taken; and if the method is adopted which I have in practice here, it renders an accident due to carelessness or nervousness at the moment of switching in impossible. The method adopted is as follows.

If alternator No. I. is running on the mains, A S 1 being closed, and it is desired to put alternator No. II. in parallel with it, the plug switches, P S 1, P S 3, must be out, the synchronising switch, S S, be open. The synchronising fuses, S F, must be of suitable size—that is to say, of such a size that any quantity of current passing that would be in any way injurious to either of the machines, or that would be liable to cause any noticeable variation in the voltage on the mains, would cause the fuses to blow. Then start up alternator No. II., and put in the plug switches, P S 2; the synchronising lamp, L, and the Cardew voltmeter, C V, will then record the effective voltage given by the synchronising transformer, S T. When the oscillation of the voltmeter needle is slow, showing that the machines are about their correct speeds relatively, watch for an opportunity when the needle has nearly attained the maximum reading, and then close the switch



S S; this will place the machines in parallel on the mains through the small fuses, S F. If the synchronism is unsuccessful, these fuses will blow, and the operation must be repeated with a fuse of 20 to 30 amperes—viz., three strands of No. 33 S.W.G. tinned copper; this need, however, never occur, but if all is well close alternator No. II., switch A S 2, and then open the synchronising switch, S S, and the plug switches ready for the next occasion.

In this way, I have put two 88-kilowatt Siemens-Willans alternators in parallel through a five-ampere fuse twice in three attempts without the fuse blowing. When using such a small fuse, however, it is necessary to run the incoming alternator on the stop-valve, as, if it were run on the governor, it would probably take a portion of the load as soon as the synchronising switch is closed, and then an excessively small fuse would give way.

If the governors are properly cleaned the current passing between two alternators in parallel, either two of 88 kilowatts, two of 210 kilowatts, or one of 210 and one of 88 kilowatts, as shown by the ammeter, does not exceed one ampere, and often no movement of the ammeter needle can be detected.

Machines should be paralleled when the voltage given by the synchroniser is on the increase; *never when decreasing*; and preferably not when stationary.

The only inconvenience that has ever been experienced in putting machines in parallel at this station has been due to the time it may take to get the machines running in synchronism should the load come on very suddenly, and the running machine so much overloaded as not to be able to keep speed. The risk of incurring this inconvenience will, however, I anticipate, be entirely overcome shortly.—Yours, etc.,

H. FARADAY PROCTOR,
City Electrical Engineer, Bristol.

Feb. 26, 1894.

THE MOUNT LOWE CABLE RAILWAY (SOUTH CALIFORNIA).

SIR,—With reference to the notice of the above electrically-worked railway in your last week's issue, may I say that that line is evidently more or less an exact copy of several such lines in Switzerland, and that as regards altitude the Marren electric railway (5,000ft. above sea-level) beats it by at least 1,900ft.)?—Yours, etc.,

C. S. DU RICHE PRELLER.

February 28, 1894.

THE LIVERPOOL OVERHEAD ELECTRIC RAILWAY.

At the ordinary meeting of the Institution of Civil Engineers, on Tuesday, February 27, Mr. Alfred Giles, president, in the chair, two papers were read relating respectively to the construction and the electrical equipment of the Liverpool Overhead Railway.

The first paper, entitled "The Liverpool Overhead Railway," by Messrs. J. H. Greathead and F. Fox, MM.I.C.E., began with a history of the undertaking, which was the practical solution of a difficulty first experienced 40 years ago—namely, the provision of better communication for passengers along the frontage (now

Digitized by Google

extending to 6½ miles) of the Liverpool Docks. The elevated railways in New York had been highly successful in meeting the wants of the travelling public, but were attended by several inconveniences. There were no parapets and no floors, the sleepers being placed directly on the top flanges of the girders. The result was that, as the railways were worked by steam locomotives, cinders, oil, and water dropped into the street; fine shavings from the rails and tyres fell on the foot passengers, and, in one case at least, a locomotive had fallen bodily into the street. Mr. A. G. Lyster, who had minutely studied the New York system, and reported thereon to the Liverpool Corporation, had expressed himself in favour of an overhead electrical railway, and after some delay an Act was obtained in 1882 by the Mersey Dock Board for the construction of a double line of 4ft. 8½in. gauge. The estimate for this, fully equipped and worked by electricity, was £466,000. The structure was intended to consist of plate girders, with overhanging continuous footways having parapets of iron lattice-work, with the rails laid upon greenheart planking; the whole being supported by columns of partial lattice-work placed in the normal structure, one on each side of the lines of dock railway. Owing to the fact that many influential members of the Dock Board were unwilling to embark upon railway management, the undertaking was in 1887 leased to the present Liverpool Overhead Railway Company, by which the line was constructed.

The length of railway at present worked was five miles, but would ultimately be 6½ miles. In the structure decided upon the columns were placed vertically under the ends of the main girders, about 22ft. apart from centre to centre, allowing sufficient width for two lines of standard gauge with the usual 6ft. way, and admitting the use of carriages 8ft. 6in. wide. Local circumstances in many cases did not, however, admit of the columns being placed immediately upon the main girders, and the latter were then carried upon cross-girders outside the line of columns. For considerable lengths, also, the columns had to be embedded in the boundary and warehouse walls. Owing to the presence of the dock lines below, cross-braeing of the piers in the usual way was impossible, and it was necessary to give to the columns and to the shallow cross-bracing connecting them at the top sufficient strength and rigidity to resist the lateral stresses due to wind pressure, and, on curves, to the centrifugal force resulting from the motion of the trains.

In carrying out the works no special difficulties arose in connection with the foundations of the piers. In places where rock was not reached, masses of concrete were deposited of sufficient extent to ensure the maximum load on the base not exceeding one ton per square foot. In excavating for the foundations the sill of the first dock made in Liverpool was discovered, and several lengths of old water-pipes, consisting of trunks of trees bored out and fitted together, were brought to light. Owing to the railway being placed immediately over the dock lines, the latter were in many cases diverted, straightened, and improved. The columns supporting the viaduct consisted of two steel channel bars riveted to two steel plates, forming a box column with all the rivet-heads outside. These columns were grouted into cast-iron sockets bedded in and bolted through the blocks of concrete. Cast-iron bumpers filled with cement concrete protected the columns from injury from passing wagons. The normal span was 50ft., but longer spans up to 98ft. and shorter ones of about 30ft. were required in some cases. Up to 75ft. span, the height of the girders above the rail-level did not exceed the platform height, and plate girders were used. In longer spans bowstring girders were used. Between the girders was fixed Hobson's arched-plate flooring, consisting of $\frac{5}{16}$in. plates bent to a radius of 12in., with a flat surface 6in. wide on the top, riveted to intervening T-bars, and made watertight by asphalte run in the V-channels between the arches. The structure was so designed that the spans could be put together and riveted up with floor complete at one or both ends of the railway, and be then transported over the completed portion of the structure to be placed in position. A special form of erecting-machine was provided, consisting of two lattice girders standing upon legs resting on the ground at the front end, and at the hinder end upon a carriage running on rails on the viaduct. These girders were placed at such an altitude as to allow the trolley carrying the succeeding span to be rolled along underneath them. On these lattice girders were placed two travelling cranes, so arranged as to lay hold of the spans on arrival, run them forward, and deposit them in their permanent position upon the columns which had been erected in advance. The average time occupied by this operation was one hour per span.

In the course of the work several opening bridges had to be provided which were described and illustrated in the paper, as were also the stations, permanent way, and rolling-stock. The total quantity of iron and steel in the structure was about 22,000 tons. The total capital cost, including equipment and all other charges, had been £550,000, or about £90,000 per mile of railway. The line was formally opened by the Marquis of Salisbury on February 4, 1893, and was opened for traffic on March 6 following. The electrical system of working was completely successful, a five-minute service of trains being maintained with perfect regularity and without mishap of any kind. On the last August Bank Holiday about 40,000 passengers were carried in the space of eight hours.

The second paper was entitled "The Electrical Equipment of the Liverpool Overhead Railway," by Mr. T. Parker, M.I.C.E.

The plant was required to run a three-minute service on six miles of double track. In designing it, curves were drawn of the energy required at any point along the line of one loaded train with various accelerations, etc., to meet the time-table service. From these curves the power required at the generating station was calculated, and four dynamos were arranged for, yielding 475 amperes at 500 volts and 420 revolutions, or 1,200 e.h.p. in all. The dynamos were of the double-line type, rope-driven, with pulley between two bearings, so that the armature could be taken out without disturbing the ropes. The electrical efficiency of the dynamos was 97·77.

The switchboard, specially designed for safety and simplicity in working, was fully described. The main current passed to the line though a main magnetic cut-out to break circuit at 3,000 to 4,000 amperes. The conductor was of steel, four square inches in section, supported on porcelain insulators. There were no feeders, and the return circuit was through the rails, which were bonded. At each station there was a cross-over road. The conductor was broken at these points, and the collector bridged across over the main rails without breaking circuit. It was necessary that the cars should be of the double-bogie type; it was, therefore, difficult to design motors to give the power necessary on standard bogie frames. Finally a type was adopted, as patented by Mr. Eickemeyer, which gave complete satisfaction. The motor occupied the front half of the bogie truck. The weight of the magnets was taken off the axles by adjustable springs, and the magnets were kept in horizontal position by a lever arm fixed to the bogie frame. Each car was complete with motor and switch gear to run independently. Two cars were coupled together to form a train. Either the driving or trailing motor could be pulled out of circuit at will. A Westinghouse air-brake was attached to the car; also the usual hand-brake. The stations were lighted by 50-volt incandescent lamps, run off accumulators fixed at the station and charged from the main dynamos.

The efficiency of indicated horse-power to electrical horse-power on the line was taken with carefully-calibrated instruments in the presence of the engineers. The tests extended over three and a half hours. The mean value of seven tests of No. 1 engine gave 88 per cent. indicated horse-power to electrical horse-power. Curves were given of the power consumed during an experimental run of one train completing 5⅛ miles in 24 minutes 57 seconds, and 23 minutes 47 seconds, with stops of 25 seconds at each station. The power required was 44·4 i.h.p. and 46 e.h.p. respectively. To compare this with actual running, curves were given from daily log-sheets showing the effects on the generating station of the alteration to the train service. The advantage of a large number of trains in pulling down the maximum current per train was

Digitized by Google

apparent. With seven trains this was twice and with 12 trains only 1½ times the average current per train. With 12 trains running, the average demand for power continuously was 37 e.h.p. per train.

A comparison of coal used when the train service varied was given. During April and part of May seven trains were running at one time, and the coal used was 22·5lb. per train mile. From June to October there had been a five-minute service from 9 a.m. to 5.30 p.m. The coal used per train mile for the four months of June, July, August, and September was 17·8lb., or making allowance for charging batteries, say 17lb. per train mile. The price of the Lancashire slack, which was used till the latter part of August, was 5s. 10d. per ton, but since that date, owing to the strike, the price for coal from various sources had varied up to 17s. 6d. per ton. Under the agreement, the contractors had to run the service of trains for 3½d. per train mile, on a full service of 2,400 miles per day, but as only 5⅛ miles of line were open they received 4d. per train mile, and for current to charge lighting batteries 7d. per Board of Trade unit. Figures were given of the actual working costs for July, August, and September, 1893, which were 3·44, 3·70, and 4·07 pence per mile respectively. The increased cost of running for August and September was fully accounted for in the item of coal, and as the railway company had not employed as frequent a service as at first anticipated (this being only 1,350 miles per day), the figures showed most favourably, it being evident that with coal at an average value, the line could be run at a cost well within that guaranteed by the contractors.

TESTING THE MAGNETIC QUALITIES OF IRON.

In our last issue we reproduced the paper read by Mr. Gisbert Kapp before the Institution of Electrical Engineers "On Methods of Testing the Magnetic Qualities of Iron." References were therein made to three wall diagrams, which we now give herewith.

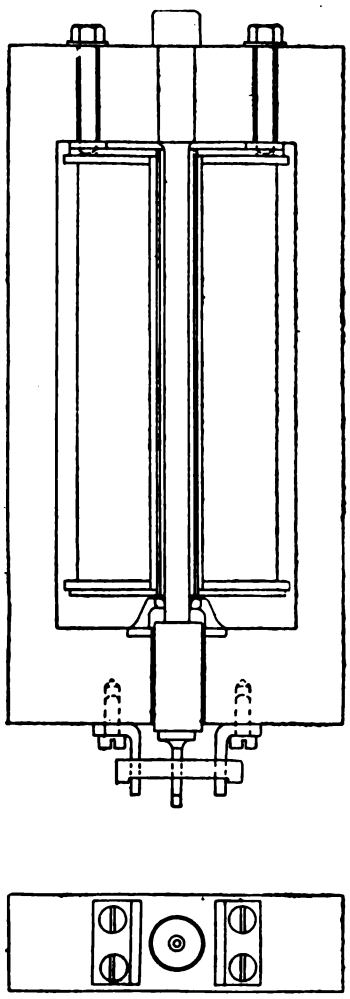

FIG. 1.—Testing Machine for Iron Bars.

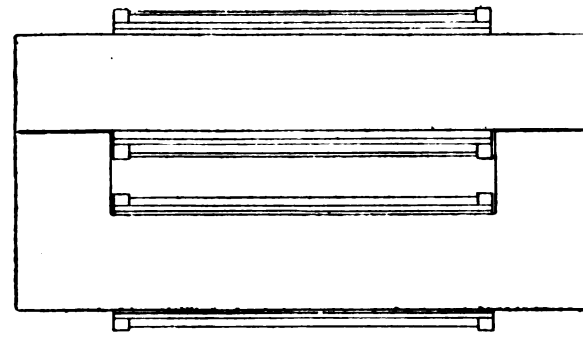

FIG. 2.—Testing Machine for Transformer Plates

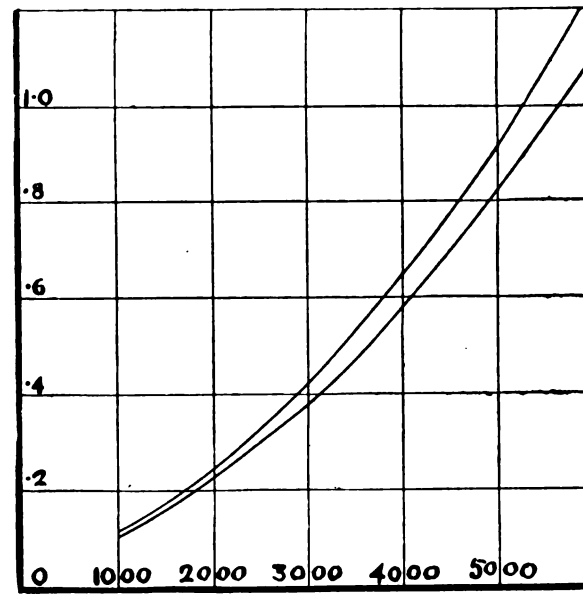

FIG. 3.—Diagram showing Average Results obtained in Testing Samples of Plates.

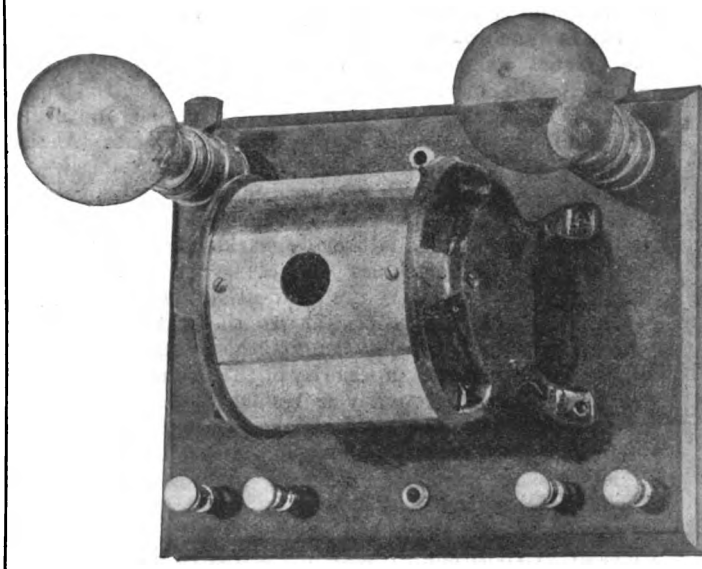
ACOUSTIC SYNCHRONISER FOR ALTERNATORS.

With the great use of alternating-current machines, and with our modern ideas of central-station practice, it is frequently desirable to run alternators, single-phase and polyphase machines, in parallel. Although alternators



Acoustic Synchroniser for Alternators.

have not hitherto been run in parallel as a general thing in the United States, the practice is not infrequent in Europe, where it has been made the subject of much study. The operation of alternators in parallel is, however, receiving more attention in America, and a device to indicate in the most delicate, yet effective, manner the exact point of synchronism in speed and coincidence of phase of two alternators has become a necessity. The requirement is

Digitized by Google

met by the acoustic synchroniser, which the General Electric Company of New York have recently brought out, and who send us the following description. It consists merely of a cylindrical iron case with an aperture in the side, each end being closed by flexible diaphragms, each of which has opposite its centre the pole of an electromagnet. In using this device one of the magnets is connected in circuit through a transformer with each of the machines to be run in synchronism. The current is then turned into the magnet coils, and the diaphragms emit a loud clear note. As the machines approach synchronism, the notes from the diaphragms approach closer in period and begin that loud, periodic sound known in music as beats. As the two machines more nearly approach synchronous speed, the beats grow slower and slower, until finally the diaphragms fall into unison and each gives out the same low, clear note. At this moment, which is sharply marked, the switch connecting the two machines should be thrown in. So sensitive and distinct is the indication of approach of synchronism, that it is possible to throw two machines together with hardly a quiver upon the ammeter in actual circuit. The immense superiority of this acoustic apparatus over the old phase lamp device cannot be disputed. It is much more sensitive, indicating distinctly the small differences from synchronism which the phase lamp fails to detect.

The synchroniser was shown by the General Electric Company in its power and mining department at the Chicago Exposition, where it attracted considerable attention, especially from foreign electricians. When it was shown to Prof. von Helmholtz, and its operation explained, he expressed himself delighted. It was a development in his own field of acoustics, and showed how electricity and acoustics could work together for scientific benefit.

SOME NOTES ON THE ELECTRIC LIGHTING OF THE CITY OF LONDON.*

BY MAJOR-GENERAL WEBBER, R.E., C.B.

(Continued from page 237.)

The facility, or otherwise, of obtaining sites for transforming stations could not be fully gauged during the preliminary stage, and space underground to be found for large conductors could only be expected to a very limited degree. If we had only known as much as experience has since shown, it is quite possible that a continuous-current system of distribution would have had as good a chance of being adopted as the alternating system. Distribution with low pressure from transforming stations entailed a network on the well-known lines, with distributing service mains and feeders. When the time arrived for the City to be divided into areas, each to be served by a transforming station, with all the stations, if not the areas, intercommunicating, the areas and points for the stations had to be approximately assumed, and the number of ways estimated that would be required under each footway throughout the whole City. It would have been, of course, easier to have first found sites for the sub-stations and then arranged the areas to be served by them; but as the main thoroughfares traversed the City throughout in all directions, there was no area that was not touched by the work requiring immediate completion, so that to be able to get the above-named 17 miles done all had to be considered in advance. The combination of casings with 1¼in. and 2¼in. pipes (see samples exhibited) require a minimum sectional area of trench varying according to locality, and if the soil below the footways had been comparatively free there would have been little difficulty in aranging the position of the ways relatively to one another, so as to suit all requirements. It was essential (*a*) to place them so that the relative positions of the ends should coincide at any rate between box and box, no matter what might be their vagaries in the interval; (*b*) that, when the trench was opened alongside of a line of pipes enclosing telegraph conductors, the mass of the iron pipes should be laid between the alternating low-pressure conductors and the same, to aid in screening the inductive effect on the smaller currents; (*c*) that the ways destined to be used for the arc lighting, and for the distribution in the street itself, should be nearest the surface. As it was, the fulfilment of these and all other conditions I have mentioned was often absolutely impossible.

The obligatory positions of boxes for drawing in and out and for access to the cables (exclusive of house service and street lamp boxes, which were only for access to the cables required) were numerous, as it was necessary to place one at every street corner, and wherever a serious change of direction occurred. Still, the lineal space of line of main occupied by boxes was, on an average, only about two yards in every 100. These boxes were made as large as possible, which is not saying much; I aimed at making them large and deep enough for a man to get entirely inside, but this was rarely possible. Owing to the obstruction underground, they are of every conceivable size and shape. Drainage and access of gas from the surrounding soil are conflicting conditions. The drainage had to give way unless some nearer outlet was evident, and the boxes made as gastight as cement and glazed or impervious bricks could make them. This question of the presence of explosive mixtures in street boxes has, as my audience knows, been several times brought to notice by explosions—one lately in the western district, on Ludgate-hill. My own view of this particular condition of danger has been to do everything to prevent the coal-gas getting into a box, and I believe this can be secured with proper precautions, apart from the occasional possibility of being able to ventilate by in-draught and out-draught ducts. The precautions are (*a*) good joints between case and case, ensured by finally passing the red-hot "mouse" through each joint after the casing has been laid; (*b*) absence of air-space between the cases and the iron sheathing; (*c*) careful sealing-in

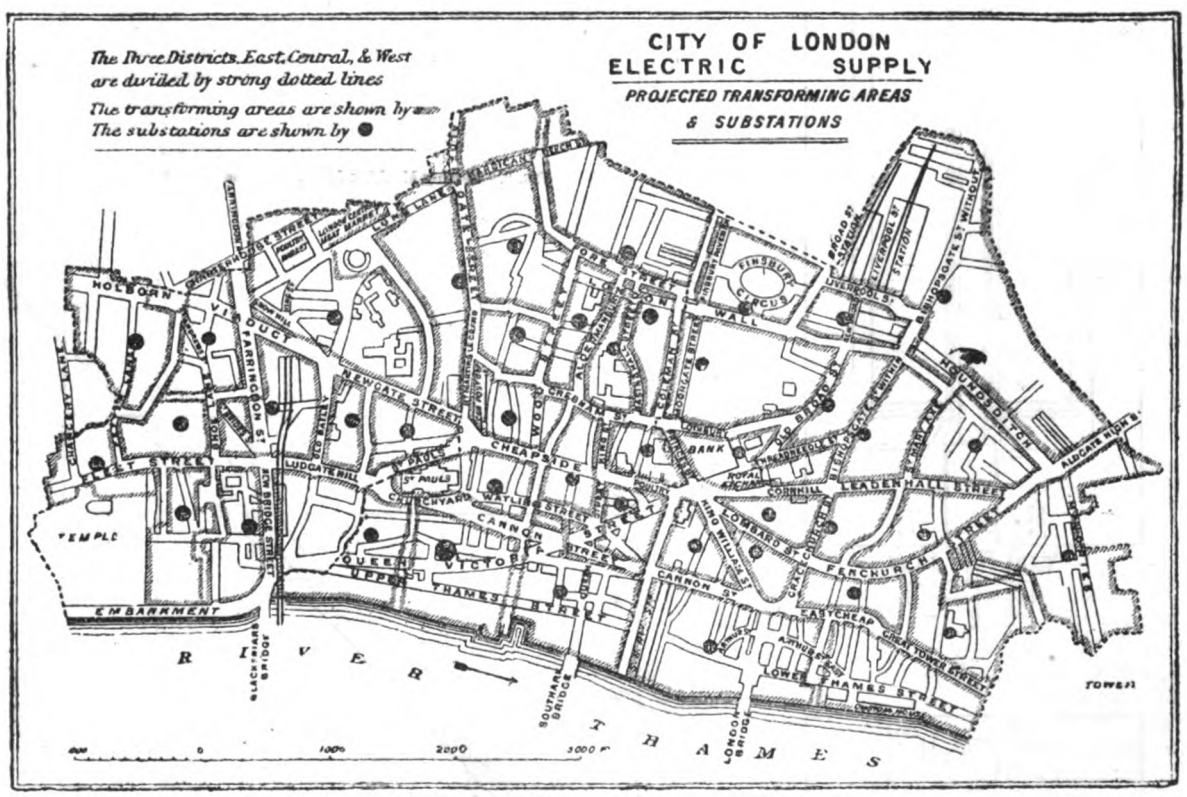


FIG. 11.—Map whole City, showing Points Transforming.

* Paper read before the Institution of Electrical Engineers.

Digitized by Google

round the iron tubes and bitumen cases where they pass through the wall of a box; (*d*) careful plugging of all "ways" not in use, and caulking with tarred yarn round the cables where they emerge from the "ways"; (*e*) the use of drainage only where the pipes are sure not to become ducts for gas; (*f*) ordinary care in the use of lights until gas is clear.

The nature of the material in and shape of the frames of the iron covers were the outcome of some experience. Nothing is better than a wide rim to the frame, roughed to prevent slipping, filled in with fine Portland cement concrete made with very hard material, and allowed some weeks to set. The bad ones—and I see there are some—were the result of want of care and bad material. The wide rim provides space for letters indicating the

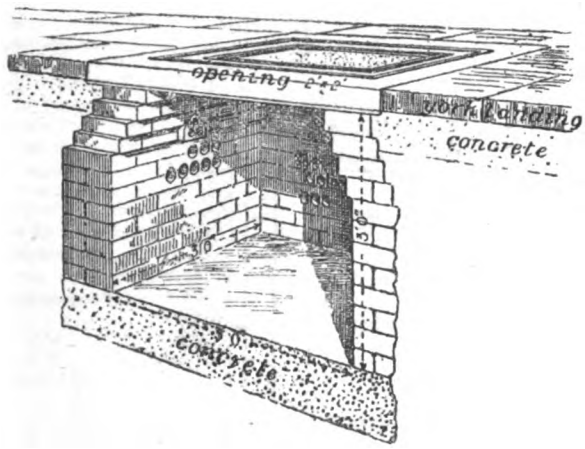

FIG. 12.—Example Street Box.

ownership of the box. In the trenches opened for that purpose all the conduits for conductors, the need for which in the future could be foreseen, had to be provided (*a*) for the public lighting high-pressure conductors, concentric in some length, separate in others (see samples of 1¼in. pipes); (*b*) for the private lighting primary high-pressure concentric conductors from the central to the converting stations, and between the latter (see samples of 2½in. pipes); (*c*) for the three-wire feeding mains to points in the network (see various sections of casing); (*d*) for the three-wire distributing low-pressure conductors of the network (see various sections of casing); (*e*) for the pilot or signal wires for the service of the company—one in each trench; (*f*) for spares and the future use of telephone conductors—as many in some places as 23—as the probable future demand indicated. (On this subject, from the point of view of the telephone service in London, I hope to be permitted to read a paper before the Institute at a future date.)

As an under-estimate of the number and size of these meant a waste later on, in having again to open the streets, and as an over-estimate would be also wasteful, it was imperative, as I have said, to make a careful study of the whole. This was done with an accuracy only diminished by the following: (*a*) the number of existing lights that might be expected within a given number of years to be replaced by incandescent lamps; (*b*) the selection of the boundaries of the areas, and approximately of the points for the transforming stations; (*c*) the desirability, though not an essential, of arranging the areas so that the difference between the consumption in each should not be too great.

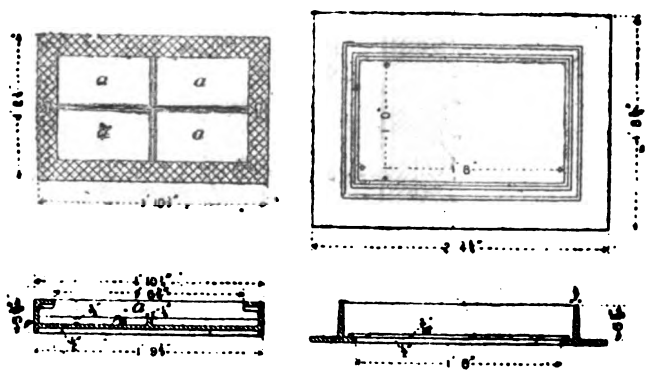

FIG. 13.—Example, Cover to Street Box.

To the difficulties in finding sites for stations, and to the unforeseen obstructions to be encountered underground generally, all these became subordinate. Careful canvassing of the City in various typical blocks of buildings (a "block" meaning all buildings situated between the nearest streets which meet one another) showed that they might be roughly classified in three, and that the number of existing lights or lamps, averaged as follows per square yard of ground space, was:

	Central.	Eastern.	Western.
First-class blocks, per square yard.	0·254 ...	0·275 ...	About the
Second-class ,, ,, ,,	0·171 ...	0·171 ...	same as the
Third-class ,, ,, ,,	0·067 ...	0·100 ...	central.

Another canvass led to the conclusion that the proportion of those existing lamps that might be expected to be replaced by incandescent lamps was:

In the first-class blocks	0·75
In the second-class blocks	0·50
In the third-class blocks	0·33

The above figures were applied, and the blocks being all classified and grouped in areas, so that each area might, as has been stated, have approximately the same number of lamps, the following results were obtained; and, although it will be a very long time before its general accuracy can be tested, I feel sure that, so far as the number of lamps is concerned, it is not very far from the truth, although the number of areas may vary very much from the estimate. For the three districts the following figures were arrived at:

INCANDESCENT LAMPS.

	Eastern.	Central.	Western.	Total.
18 areas	139,900	—	—	—
14 ,,	—	100,750	—	—
12 ,,	—	—	99,547	—
Total, 44 areas	—	—	—	340,197

If these are 8-c.p. lamps of 33 watts, this will give a load at the lamp terminals of 11,226·5 kilowatts. With 96 per cent. in the transformers at full load (the efficiency specified under the contract), and 5 per cent. loss in the mains, primary and secondary,*

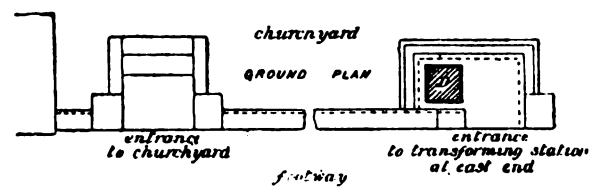

FIG. 14.

the output of alternating current of the three stations—namely, 12,100 kilowatts—is not far short of 12,236 demand, the maximum possible load, so that with 80 per cent. of the lamps alight there would be nearly 20 per cent. spare generating plant. If it may be assumed also that each 8-c.p. (33-watt) lamp uses 18 units = 6,123,546, with 20 per cent. spare, the load factor comes out = 13·8. The design of 44 converting points in those districts required that, including spares, each transformer station should have, on an average, 275 kilowatts capacity. The three first permanent sub stations, the sites of which were secured by, and the structures designed by, myself were: (1) Pancras-lane (Bennet shere-hog), with space for transformers having a capacity of 450 kilowatts; (2) Nicholas-lane (St. Thomas Acorn), with space for 480 kilowatts; (3) Queen Victoria-street (St. Nicholas Cole Abbey)—this is a double station, and has space for 648 kilowatts. Of these I only show the design of the first, it being situated under exceptionally difficult conditions. (See Plan No. 14, etc.)

TRANSFORMATION.

As has been said, little progress could be made with the selection of sites for permanent transformer stations before July, 1891, as the general scheme upon which their relative positions much depended was still under consideration. To distribute the current generated in the pioneer stations, three temporary transforming stations were improvised—viz, one in Queen Victoria-street, in the basement of No. 47; one in the basement of the Mansion House; one in St. Swithin's-lane, under a restaurant. In no case were these suited to become afterwards permanent stations, both on account of size and circumstances of surroundings. In the transformers first delivered the secondary windings gave a pressure of one-twentieth that of the primary; and as the current is delivered at an E.M.F. of about 2,050, and it had to be

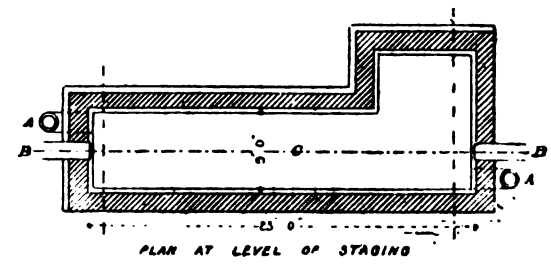

FIG. 15.

distributed in the three-wire mains with an initial pressure of about 205 volts, they had to be coupled two in series—an arrangement which would disappear with the delivery of the contract transformers.

It early became evident that the price, by way of rent, that would be demanded for adequate space in, and access to, existing buildings, was prohibitive in the more costly areas. For instance, in Lombard-street, where every square yard is said to be worth £1,000, it can readily be conceived that £500 a year was asked for a small room in the basement. With this in view it behoved us

* It is quite certain that this ideal condition of efficiency can only be achieved when a completed system is at full work lower loads it will often go down to 76 per cent.

Digitized by Google

to look for what we required to the space under those portions accessible to the public, or not available for building purposes. Careful searching showed that many engineering and financial difficulties existed For instance, at some points where there was evidently ample space below the surface, a prohibitive price was asked for the means of access to it through private property; and, again, at many such points, space for access within the area used by the public could not be obtained, for various reasons of public convenience and safety. In time our attention was turned to the old City graveyards, and, after long negotiation with the parish authorities, and with the Consistory Court and the Commissioners, leave was obtained at a fair cost to use a small portion of two of these open spaces in Pancras and Nicholas lanes, so as to provide shafts for descent to the contiguous chambers to be constructed by leave of the Commissioners under the foot or road ways. But, even with this facility, the space below was in one case—namely, Pancras-lane—extremely limited, through the

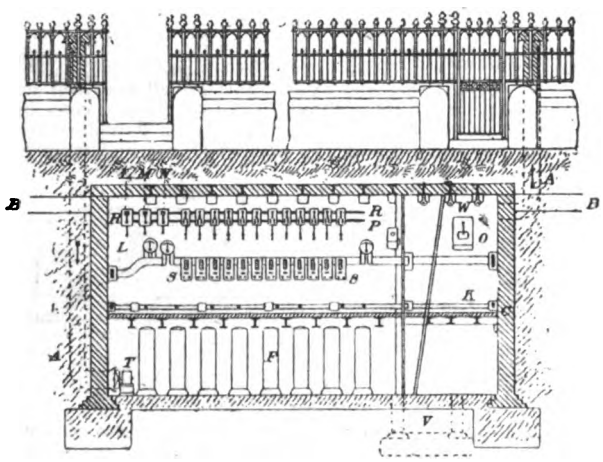

FIG. 16.

existence of large main sewers and water and gas pipes. In excavating, large quantities of human bones were met with, which had all to be transported carefully for extramural re-burial.

The drawing shows the structure and the conditions of housing the transformers and switchboards and connections. Under such circumstances every inch was important, and it was to the suggestion of my chief assistant, Mr. Nisbett, that the plan of placing the transformers, F, below the floor was adopted in that station. Height was the most elastic dimension, and it will be seen that the attendant standing over the transformers on a stage, C, has sufficient headway to stand up and attend to the board, S, one on the north, another on the south side. The floor of this stage is made of wooden squares, each of which can be taken off independently, and the top end of the transformer underneath exposed. When required to be removed, it is lifted by tackle suspended to a ring (as at W) in the arched roof, and, being received on to a

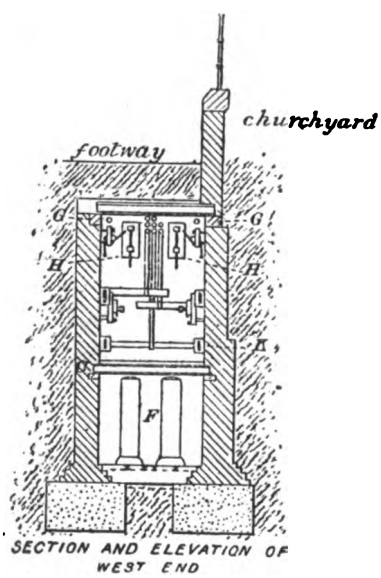

FIG. 17.

hand-truck, it is moved along the floor to the bottom of the entrance shaft, and there, by other tackle, carried by a tripod standing above on the dwarf walls, lifted up to the surface, where it can be lowered on to a suitable trolley and taken away. B shows where the conduits enter the station at the east and west ends; D is the entrance for access to the descent by ladder into the staging; F indicates the 18-kilowatt transformers; G, the position of the primary 'bus bars on each side; H, the main primary switches; K, the low-tension middle bar which runs round the tension; L and N are switches for connecting at high tension with other transforming stations; M, a switch to divide the station in two for repairs; O, a recording voltmeter; P, the telephone to the generating station; R, one pole of high-tension bar, with a switch to every two transformers, and Brush-Mordey fuses; S, low-tension switches on 'bus bar, with a switch to every two transformers, and separate fuses; T, motor and fan for ventilation. Drainage by a sump, V, and ventilation by large upcast and downcast shafts, A, A, are provided, as well as means of telephonic communication, P. The cost of the builder's part of the structure, when completed, is about £430, with an annual charge for the wayleave of about £5.

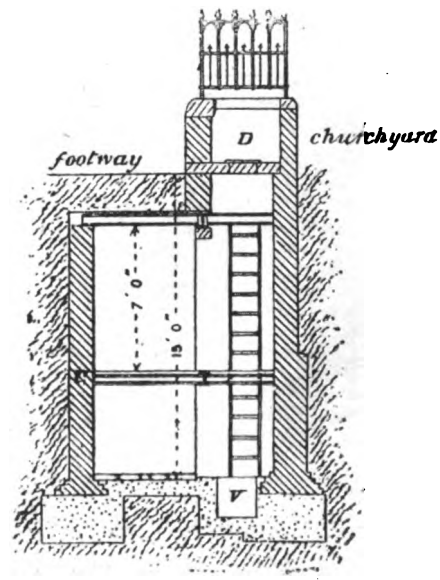

FIG. 18.

The honeycomb space under the staging floor should be able to receive 45 10-kilowatt transformers, of which 40 may be assumed to be in full use—the rest spare. The cost may be considered in the following way:

The present value of £5 a year for 21 years, at 5 per cent....	£64
Cost of building construction	430
Cost of transformers and fittings, as per contract.....	—
400 kilowatts, at £7 per kilowatt	2,800
Add 5 per cent. for supervision and contingencies	182
Total cost of a transforming station (having a maximum space for 450 kilowatts)	£3,476

To arrive at the capital cost of the plant between the generating stations and the low-pressure feeders, it is necessary to add the cost of two concentric mains; and this I have taken from a

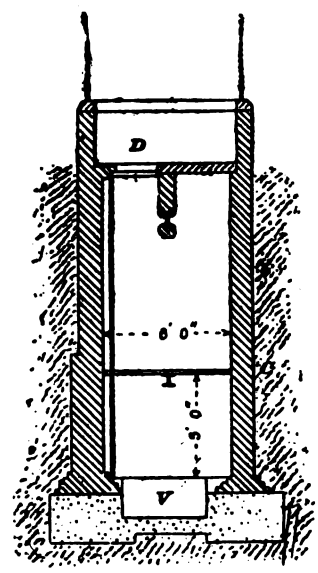

FIG. 19.

table that I prepared which enables me to appropriate with very fair accuracy between the conduits for various purposes the cost of the underground work. In this case the distance is about 1,200 yards.

Carried down	£3,476
Two 2½in. wrought-iron conduits, at 4s. 4d. per yard.....	520
Two 0·154in. concentric high-insulation 1,200-yard cables drawn in and connected	1,150
These figures give a total capital outlay of.....	£5,146

Digitized by Google

which will be repaid, interest and principal, at 4 per cent. in 21 years by, per annum, £161 ; to which should be added at least 2½ per cent. depreciation and repairs—say £136—and £70 for attendance and small stores—total, £367. Again, assuming a total consumption of about 18 units per 33-watt lamp fixed, and 12s. the gross earnings per lamp per annum, and allowing 96 per cent. efficiency as before, and the equivalent of 15,000 8-c.p. lamps connected with this one station, or, say, £9,000 per annum, the above annual charge will represent 4 per cent., being a standing charge on every unit sold. A useful comparison may be drawn between the cost of these 2,000-volt mains and low-tension mains at 200 volts from the generating station to the same distributing centre. A loss of 2 per cent. in the high-pressure mains, and of 4 per cent. in transforming—total 6 per cent.—in the former, may be fairly balanced by a loss of 15 per cent. in the latter. The additional size of the low-tension plant is counter-balanced by its lower price. The low-tension main, required to carry 400 kilowatts at 200 volts pressure through 1,200 yards of distance with a loss of 15 per cent., would be about 4 square inches of copper in each outer conductor, and 2 square inches in the middle wire. Such a line, using the largest insulated cables made, and drawing them into 10 3in. "ways" of casing, would cost more than £15,660, representing an annual charge of £490, or 5·4 per cent. on each unit sold. Mr. Crompton will, I hope, give us the cost of the same sections of bare copper strip laid in culverts on his system, if he can keep his culvert within 160in. sectional area.

marked respectively, C^1, C^2, C^3, C^4, and E^1, E^2, E^3, E^4. The diagram map shows eight central districts in the City which were presumed to be those richest and having the largest immediate demand. He agreed entirely with me in deprecating the provision of mains through long streets, as had been laid out in the pioneer contracts, and saw the need to break up long streets into sections, each such section to be supplied as part of a compact surrounding area. The exact delimitation, even of the individual areas, he considered a less important matter than their compactness, solidity of work, and efficiency of supply. At that time, and with the same gentleman, the question of automatic switching of a bank of transformers was discussed. It was a novel one as regards experience. We regarded it as essential that, although at first manual regulation with daily shifts of attendants could not be avoided, eventually it would have, for economical reasons, to be done automatically. And in connection with this the inventions of Messrs. Gordon, Mordey, Tomlinson, Ferranti, and Kapp were considered. Of these well-known electrical engineers some are present, and will, I hope, give us the benefit of their remarks on this very interesting and important part of the subject.

Execution of the City Street Work.

Although it may not fall to the lot of any present to have to carry out a similar work under the same conditions, it seems to me that a short account of a portion of what was done in the City streets may prove instructive to engineers. Our papers are generally very full of technical interest, but few ever narrate the

Fig. 20.—Centre of City.

It being very desirable that the works of distribution in the City should receive efficient criticism, Prof. S. P. Thompson was (at my suggestion) asked in October, 1891, to advise and report, which he did ; and I regret that circumstances permit me only to give the sense of his reports. He dwelt with the subject of any possible advantage from the use of low-tension dynamos and step-up transformers at the generating station, in comparison with the generation and transmission at 2,000 volts as specified, without recommending any change in the designs. He recognised the extreme difficulty, in certain thoroughfares, of getting ways for the laying of conduits ; in certain rich blocks, of getting a cellar for a distributing station ; and the necessity for the principal routes to run north and south, not east and west, because the generating stations were on the south side. As an example, he regarded Cheapside as practically an impassable street ; as it runs east and west, "as almost useless for the purpose of a route." That shops in it must be approached through side streets and from the rear he considered in reality as no disadvantage, "for lamps are wanted most, not in mere frontages, but in back offices." He thought that there was the less need in the central areas to trouble about keeping them of equal size, since the distances from one sub-station to another were necessarily short. Having secured a sub-station in any one spot, it was easy to estimate, from the accommodation it affords, the extent of the district which it will subserve. He told me that the general plan I had prepared of distributing the alternating current at a pressure of 2,000 volts by mains to transformer sub-stations "could not be improved upon," and agreed entirely in principle with the general plan of distribution as provisionally set out in the maps shown this evening ; and, further, approved generally the size of areas assumed in those maps to be suitable, and that the richest areas so mapped out are the eight areas surrounding the Mansion House (see plan) practical working engineer's experiences. This must be my apology for some diffuseness. Enforced inaction for an engineer is always irksome, especially as he is well able to anticipate the loss and overwork that must follow through dilatoriness of those whose duty it is to make up their minds. Such was my position between July and December, 1891, when valuable time was lost, and heavy and pressing work requiring to be completed by the end of February, 1892, had to be suddenly put in hand. Fortunately, I had foreseen the rush that would come, and had engaged and organised my office and staff so as to be ready to go to work when required, and had also called for and received tenders for the various kinds of articles of plant and materials (several of which had to be specially designed) that the work would require.

The chief difficulties that had to be faced, besides those inseparable from street work in the City, were (1) the time of year (all the fine autumn had been lost), with its wet, mud, and fogs ; (2) the difficulty of readily finding a sufficient number of suitable foremen to take charge of such work ; (3) the inconvenience caused to the public by having 100 yards of footway "up" in nearly 30 different places at one time. My estimates of the cost of the work had been based on the assumption that it would be carried out under own staff, by hiring labour, and by purchasing tools and material, with a reasonable rate of progress. There was no doubt whatever that the intermediary of contractors would be wasteful, even although it was easy to find road and paving contractors in every city of the kingdom. Time being precious, and the Commissioners threatening, my ideal could only be partially carried out. Tenders had therefore to be called for for separate sections of the obligatory streets ; but here the obvious difficuly of price had to be faced. No contractor would quote to lay anything under a City footway without at least 100 per cent. margin, unless he could first take up the surface.

Digitized by Google

But this first taking up was not permissible. Tenders under such conditions were obviously objectionable. Then, considering that we wanted several contractors to go to work at once, besides our own gangs, it would have sent the price up a hundred-fold if their tenders were to include the supply of tubes, cases, and material, because they would have been competing for such unprecedented quantities in the same market. There was only one course to follow—namely, (1) to purchase all the materials ourselves; (2) to prepare a specification and schedule of measured prices especially suitable and confined to the kind of work; (3) to pay for the work under measurement.

As regards the first—namely, the material. Wrought-iron tubes, although a considerable stock is to be found amongst makers, are not held in quantities representing hundreds of miles, particularly of the quality of iron, and lap-welded, that we wanted. Our tests of samples were necessarily hasty, but the steam-hammer, though rough, gave us a pretty fair indication of toughness. The very fact of so large a quantity being wanted, instead of enhancing the price, enabled us to do what is called "break the ring," and I believe it is one of the very few cases in which tubes have been sold some 20 per cent. below "ring" prices. All the tubes were treated with Angus Smith compound. As regards the Callender-Webber casing, there was only one maker; but here, again, foresight on behalf of the City lighting had a long time previously provided for special rates in favour of that particular work. At the same time I cannot speak too highly of the great efforts of Mr. Tom Callender at that time to extend his company's means of output, and that at very short notice. I remember that at one time the bitumen we were bound to lay underground in January, 1891, was still, in Christmas week 1890, on board ship in the chops of the Channel.

As regards the second—namely, the specification and schedule (of which a copy may, if the Council permits, be attached)—it is sufficient to state the former consisted of 44 clauses, and that the latter had 55 items, which the tendering contractors were asked to price. But even with these precautions it was felt that, in the case of the most difficult streets, no contractors could be asked to tender at all except they were allowed to charge for whatever they paid out, and then with no obligation to meet all the liabilities for damage to person and property in the most crowded and intricate places in the whole world. To our own engineers and men the work in such places as Cannon-street, Thames-street, Cheapside, Poultry, St. Paul's-churchyard, and around the Bank, etc., was allotted. In the 22 streets in the eastern and central districts which remained to be dealt with at the end of December, the total length of trench to be excavated, and completed with conduits and boxes, was nearly 24,000 yards, of which 9,700 was allotted to the company's gangs. There was only one month to do it in to carry out the conditions of the contracts with the Commissioners. Three contractors at first—afterwards a fourth was added—competed successfully. (Nine firms tendered.) The abstracting of all the tenders showed a variation on the average work between £188, the highest, and £79, the lowest, per 100 yards of work. The highest tender accepted was at the rate of £128 per 100 yards. The same work in the more difficult ground done by the company's gangs cost only £60, including the cost of the plant used by them. The average cost of the materials was about £118 per 100 yards. The actual cost of the work essential to be completed in February was about £59,000. The maximum rate of progress was attained at the beginning of March, 1892, when 1·65 miles of trench was completed in six days' work. An analysis shows that the 4,260 yards by one of the contractors, at £128 + £118 = £246, cost £3,069 more than it would have cost if done by the company's gangs; that the 4,010 and 5,270 yards of the two others respectively cost £2,560 and £1,265, correspondingly, more; giving a total of £6,894. But it may fairly be said that if the contractors had tendered to do the work when the days were fine and long, their prices would have been 5 per cent. less—say, £723. It may be instructive to young engineers present to realise that if the adverse conditions I describe could have been avoided, a saving of about £7,617 on what actually cost over £30,000 would have been effected; and that is exclusive of the advantages in the minor results in the form of better "finish" when the work is done under one's own foremen. If the same work had been carried out at the rates of the highest tenders accepted, it would, including material, have cost £72,000, and if entirely in the way my estimates contemplated, the costs would have been, correspondingly, £40,000; but in neither event, having been begun in December, would it have been all done, as was essential, early in February.

A glance at the map (see Plan No. 20) will show that in the heart of the City there are eight transformer areas designed; and, naturally, as soon as the main thoroughfares were completed, to the completion of conduits in the lesser thoroughfares, streets, and courts of these areas was immediate attention turned. The amount that had to be paid for the work done in the streets by the pioneer contractors (already referred to) was £22,850, which, added to the previously stated amount, came to a total for the main thoroughfares of the eastern and central districts of £81,850. In the whole City there are 92½ miles of frontage, and in the eight special areas there are 22,000 yards. If the average demand for lamps is 2·1 per yard, we get 46,200, or about 6,000 per sub-station area; but, being the richest areas, three lamps per yard, or 8,500 per acre, was estimated. By March, 1892, the cost of the work (not done by contract) could be pretty closely detailed, and the cost of the conduits in portions came to a little over £17,000; giving a total for the completed street work in the main thoroughfares and eight sub-districts of the eastern and central districts, exclusive of conductors (except a small quantity of cable provided under the pioneer contracts, which is included), of £98,850. Of this, the length of trench completed by July, 1892, was 43,000 yards. I have little doubt we shall be told that most of the lighting in those areas is with 16-c.p. lamps. In this respect, I think it is evidently the wrong initiative policy to try to make up a big load before you are ready, in order to make a fair show, instead of keeping it down when first starting by encouraging in every possible way an economy of light by the use of 8-c.p. lamps. It is well known that I have been from the first an advocate of this policy, and I now attribute our measure of permanent success at Chelsea as being large due to it.

It will be readily understood, by a glance at the plan, that the streets bounding the areas having been completed with all the "ways" actually necessary, and that could be put in, the internal cross-streets could be provided with all that the future load could possibly demand for feeders of any size. A more precise idea of the cost of this kind of work laid in streets presenting exceptional difficulty is given below. In an example of the streets in question only eight "ways" could be introduced under the footways on each side—viz.:

	Ways.
In Callender-Webber casing	3
In 1¼in. tubes	4
In 2½in. tubes	1
Total	8

The length of the two sides, taken together, inclusive of the lengths occupied by boxes, is 1,328 yards.

The cost of taking up the surface and temporarily relaying it, at 3s. 9d. per yard lineal, was	£250
Laying conduits and pipes, at 1s. 3½d.	85
Cost of conduits and pipes, at 8s. 6d.	718
Superintendence, storekeeping, cartage, sundries	78
Small stores and blacksmith's work	27
Wear and tear of plant, and contingencies	116
Cost of draw-boxes and service-boxes where actually required	99
Approximate cost of restoring the surface, performed by the Commissioners' contractors, and on their schedule	554
Total	£1,927

Or £1. 9s. yer yard lineal of trench, exclusive of cables.

The equipment of this line with cables of the following sections—namely, two of 0·3 square inch section of copper for low pressure, one of 0·15 square inch section of copper for low pressure, four of 7/16's for high pressure, one of 0·158 square inch (concentric) for high pressure—costs, in addition, £2,037; giving a total cost per yard lineal, inclusive of cables, of very nearly £3.

Including casing used for house services, the total length of ways in bitumen concrete casing laid in the streets and areas named up to July, 1892, was:

In casing unsheathed with iron	4,356 yards
In casing sheathed in iron	148,068 ,,
Total	152,424 ,,

Or over 80 miles. The internal diameter of these varied between 1in. and 2⅜in. The largest proportion of these were of the triangular form (exhibited this evening). The total of 1¼in. wrought-iron tubes laid was 173,000 yards, or 98 miles; of 2½in. wrought-iron tubes, 164,000 yards, or 93 miles. Total of ways of all sorts laid in the City between December, 1891, and July, 1892, 271 miles.

Of the Raworth-Callender-Webber conduit, 212 yards, containing four ways, were laid in Queen-street. This was an experiment, and is an example of paper-lined ways bedded in bitumen and laying in cast-iron troughs, with separate cast-iron joint-pieces, and cast-iron covers bolted down. This latter system, called the "Callender-Raworth-Webber," in which I am joined with those gentlemen by an act of courtesy on their part, is chiefly attractive to me through the possibilities it offered for the use of bare stranded copper. Since then I have brought out, in conjunction with those gentlemen, a further development, being a combination of the two systems above mentioned, called the "Webber-Callender-Raworth" conduit, which I hope may be a step in advance in that much-to-be-desired direction. The durability of the paper has yet to be tested, but of this I have little doubt, if it is thoroughly impermeated. The only drawback is that they cannot be easily bent during laying, and that, as laid in the City, the cast-iron cover has to be cut through with a cold chisel to make a house-service connection. The sheathing of the Callender-Webber cases was mostly made of No. 22 gauge sheet mild steel, which covered the three sides of a triangular, and the four sides of a rectangular case, then secured by studs or cut-in pieces, or 1½in. hoop iron riveted, and the whole painted over with a bitumen solution. Sheathing for these cases was first used in the City work. As is well known, the cost of the casing when it is triangular in section and has three ways of 1¼in. diameter each, is without sheathing 1s. 11d. a yard, which is 7¾d. for each way. The same sheathed costs 2s. 10d., or 11¼d. per yard. Nearly all the 1¼in. wrought-iron tubing laid (generally four tubes under each footway throughout)* cost 9½d. a yard, which was an exceptionally low price for the reason I have already given; this is, against the first cost per yard of ways of the former material, less by 1¾d. per yard. The advantages of the bitumen case, I think, more than counterbalance this: (1) durability; (2) there is less labour in making two bitumen joints than three screw joints (the former are 6ft. apart, the latter 12ft.); (3) the bitumen is more easily cut to lengths and bent than the wrought iron; (4) there is no risk of rust sealing in the cables after they are in the

* Two 1¼in. tubes are destined for the public and two for private arc lighting series cables.

Digitized by Google

bitumen ways, as often occurs with iron ways. When you come to compare the 2½in. ways in bitumen and wrought iron, the costs are as follows: in the former each way in a sheathed case costs—with triangular section, three-way, 1s. 9½d. per yard; with rectangular section, three-way, 2s. 1d. per yard.

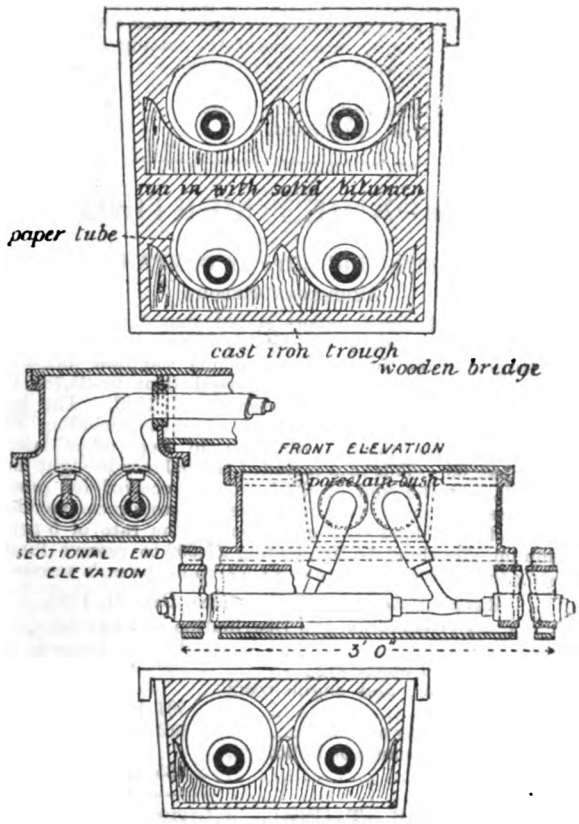

FIG. 21.—Callender-Raworth-Webber Conduit.

This at once compares favourably even with the exceptional low cost of our 2½in. wrought-iron tubing used in the City, which was 2s. 6½d. And when there are six 2½in. ways in a case the cost per way comes out at 1s. 5d. per yard, and a large economy is at once evidenced—increased if the cost of sheathing is avoided. But it must at the same time be noted that where we laid 18 (and mere) 2½in. tubes in the same trench with other conduits—for instance, throughout Thames-street—we might not have found room for three more six-way cases, which in cross-section occupy more space than 18 2½in. tubes. I have not referred to the western district, the contract for the public lighting of which did not require completion before November 5, 1892; but it may be stated that this work alone required 11,614 yards of trench, which, at an average cost of £1. 12s. 1d. per yard, would cost £18,630, exclusive of spare tubes for other purposes.

CONDUCTORS.

As has been stated, the primary alternating-current conductors were concentric 0·154in., with high-class insulation; the high-tension continuous-current conductors were 7/16's concentric, except where the lamps are connected, also with high-class insulation; and the secondary conductors on the three-wire system of various sizes has Callender extra standard type insulation. The two first were drawn into 2½in. and 1¼in. wrought iron tubes respectively. The last was drawn into the three-way Callender-Webber casing, manufactured of three sizes—namely, with 1½in., 2in., and 2⅜in. ways; in each of those the third way is smaller than the other two. The largest were for feeders where necessary, and the two smaller for distributors. In the eight sub-district areas shown on the map (Plan No. 20) it is seen that no consumer's terminals would be more than 100 yards, measured along the main, from a transformer station; consequently, allowing the Board of Trade drop of 4 per cent. above and below the normal, the section of cables first drawn in, the maximum areas of the three conductors, taken together, was ⅜in., and very few feeders except quite short lengths were necessary. It was considered that for a considerable time to come this would comply with a demand of at least three lamps per yard of frontage, the frequency of transforming stations being maintained. The impedance due to retardation was therefore negligible with those sizes. The cable specifications giving the special conditions under which the manufacturers had to tender (of which a copy will be attached to this paper) had some special features—namely: The same results of insulation as were prescribed for the tests at the maker's works were required after each length of cable had been drawn in, in the presence of the maker if he wished it, and before joints were made in it. The maintenance of the insulation, except at joints, was guaranteed by the maker during three years from the date of it being drawn in, and if within that time the dielectric had deteriorated the maker was to replace the cable.

With a view to the company having the advantage of the market rate of the price of copper at the date of the quotation, the contractor was required to state the number of tons of copper, made up in insulated cable, for which he would receive orders at that rate during one year. As it became soon apparent that in each of the eight sub-districts above referred to separate transforming stations might not be obtainable, the question of a distance between them probably greater than had been calculated on required consideration, and the consequent enlargement of the sectional area of the copper in the conductors. The first point that had to be considered was as to the saving that could be effected by the use of hollow-cored cable. With alternating currents having a frequency of 100 there is an inequality of distribution of the current over the cross-section of the cable, and for practical purposes the penetration may be regarded as not exceeding ¼in. from the outside of a cable of stranded copper, and therefore, if above ½in. diameter, the copper in the centre of the strand is not useful. These conditions led to the adoption of the Callender hollow cables for sizes varying between 0·4 and 0·7 of an inch sectional area as the simplest and cheapest form. For instance, such a cable having half a square inch section of copper was made up of 38 No. 10's or 30 No. 9's, in two layers round a hempen core, when the outer diameter of the copper is 1·05in. For anything over ¾ square inch section of copper it was apparent that some form of multiple strand would have to be adopted; but for the supply then contemplated (even with only 600 amperes per square inch density) the maximum of 0·7 of a square inch was sufficient to provide. As regards joints and jointing—that very important matter both in first cost and maintenance—I had examined every form that in 1891 had been before the electrical engineering world, and at that time had no reason to alter the opinion formed from long experience that only when forced to adopt anything else by the construction or dielectric of the cable, could I recommend anything more simple, practical, or durable than the joint made of the same material, and of the same form of covering as the cable itself, and this is applicable to both straight and T joints. As regards the experience gained by the company in the matter of their mains since July, 1892, I shall hope the Institution may have the most instructive information from the engineers who carried on the work after I retired from it. The best qualified is Mr. G. H. Nisbett, who since the autum of 1890 had been my right hand in all matters connected with electrical distribution, and whose intimate knowledge of every part of the City work made it absolutely essential that he should pass from my service to that of the company when I left it. I cannot refrain from also mentioning here two indefatigable assistant engineers on the same duty—namely, Mr. Buck (late R.E.) and Mr. Bates.

(To be continued.)

PHYSICAL SOCIETY.

At a meeting of this society on February 23, Prof. A. W. Rücker, M.A., F.R.S., president, in the chair, Mr. J. W. Kearton was elected a member of the society.

A "**Note on a New Electrical Theorem**" was read by **Mr. T. H. Blakesley, M.A., M.I.C.E.** Two or more dispositions of E.M.F. in any network of conductors which produce at every part of the network the same currents are defined as "equivalent systems." The following theorem is then stated and proved: in any system of conductors possessing seats of E.M.F at any number of points, if any of these sources be moved along the various bars of the conducting system, and where a point of junction is encountered, each becoming a seat of the *same* E.M.F. in *each* of the newly encountered bars, then the disposition at any moment is equivalent to that at any other moment, and therefore to the original disposition. Equivalent systems might also be defined as being such as produce equal expenditure of power in each part. From the above theorem the following propositions are deduced by the author: first, that if any closed surface contains a portion of a network, then an E.M.F. in any bar cutting the surface can be replaced by equal E.M.F. (in opposite directions as regards the surface) in all the other bars cutting the surface, without disturbing the current in any part of the network; second, if two systems of E.M.F. be equivalent, one may be derived from the other.

Prof. C. V. Boys, F.R.S., read a note on the "**Attachment of Quartz Fibres.**" When torsion fibres are required to carry large weights approaching the breaking weight, the ordinary method of attachment by shellac is not always satisfactory, for if the part of the fibre in the cement is twisted or bent, the yielding of the shellac causes uncertainty of zero. To avoid these troubles Prof. Boys has devised and perfected a method of soldering the fibres, full details of which are given in the paper. After selecting a fibre of the right diameter and length, small weights are fixed on the ends by shellac. The end parts are then cleaned by dipping in strong nitric acid, washed, silvered, and electro-coppered. The weights are then cut off and the coppered ends soldered to tags of tinned metal foil, chloride of zinc being used as a flux and its capillarity serving to hold the ends to the tags whilst the latter are heated. The superfluous copper and silver are dissolved off by nitric acid, the tags and solder being protected by beeswax. After washing in boiling water the fibre is ready for use. Melted shellac is used for securing the tags to the torsion-rod and suspended body. Several ingenious details of procedure to avoid capillary difficulties in the cleaning, plating, and washing processes are described in the paper. If fibres are required to conduct electricity, they are silvered and washed after the tags have been soldered on. Such fibres the author considers essential

Digitized by Google

for making connection with electrometer needles of the greatest delicacy, for liquid connections are fatal to stability. Methods of rendering fibres visible by smoking with arsenic or magnesium are mentioned in the paper. At the meeting a perfectly circular hole, $\frac{1}{5000}$in. in diameter, made by soldering round a quartz fibre, passing through a hole in a metal plate and then drawing out the fibre, was exhibited under a microscope. **Mr. Inwards** asked if the shellac used to secure the tags was melted or dissolved. **Mr. Blakesley** enquired if silvering fibres did not destroy their perfect elasticity. **Dr. Sumpner** wished to know if any data as to the relative torsional rigidity of silvered and unsilvered fibres had been obtained, and if the electric resistance of silvered fibres had been determined. **Mr. Watson** said silvered fibre had been successfully used in electrometers. As regards their torsion, he had found it differ from day to day, and the resistance varied enormously. In reply to a question, **Prof. Boys** described the exact process of soldering the copper fibre to the tags. As to the torsion of silvered fibres, he would not expect much increase, as the fibre was very thin. He also thought the elasticity would not be destroyed, for silver and gold make very good torsion wires.

THE BOARD OF TRADE AND ELECTRIC TRACTION.

As stated in our last issue, a conference was held last week on the proposed Board of Trade regulations for electric traction at the Board of Trade offices, Sir Courtenay Boyle presiding. We quote the following report from the *Times*:

The Chairman said the regulations they had met to discuss were under clauses which had been inserted in certain Bills, and which would probably be inserted in all Bills as model clauses, in consequence of the action of the joint committee of last year, and would therefore have general application to all instances of traction by continuous currents. Parliament, with a respect for the discretion and decision of the Board of Trade which was very flattering, but which caused a considerable amount of labour, had decided that upon the Board of Trade should devolve the duty of settling the regulations governing the conditions under which traction should be used.

The regulations were then discussed *seriatim*.

Sir Frederick Bramwell, speaking on the regulation which provided that when any part of an electric return was uninsulated it should be connected with the negative terminal of the generator, and the electric company might make one connection to a main for water supply, said that as the regulation stood this could be done simply with the consent of the water company, and he suggested that the consent of the owner of the pipe should be necessary.

Mr. Monier Williams said the gas companies had a similar objection. There was no clause as to damages in the regulations.

Mr. Aspinall thought the water-pipes might be seriously damaged by electrolysis through connection being made with the water-mains.

Sir Courtenay Boyle said they were entitled to see that they were sufficiently protected in these regulations, but they could not ask him to insert the power to award damages, which was a matter for legislation.

Sir Henry Oakley said that, with regard to block signalling on railways, he was advised that it was quite possible that the escape of electricity from some of these high-pressure traction wires might actually reverse the signal intended to be given of "danger" into one of "all right." He thought it should be clearly understood that if the Board of Trade could not provide the protection the railway companies sought they must oppose any and every traction provisional order or Bill.

Sir Courtenay Boyle said the Board of Trade required no pressing on the part of the railway companies to avoid by any possible means any such danger in regard to block signalling.

Mr. Siemens said it really took three manipulations before the block signalling of a railway was interfered with. As long as railway companies had got the earth current, any current, meteorological or otherwise, would interfere with them as much as a current from tram line.

Mr. Langdon replied that meteorological currents were only occasional, but a traction current would be continuous.

Major-General Webber thought it would be very unwise to protect the railway companies in these regulations in regard to their block system, as that might result in their not incurring the small expense which would safeguard them.

Sir Courtenay Boyle said he thought the best plan would be that Major Cardew, the electrical expert attached to the Board of Trade, should go down into Staffordshire and consider the experiments made there by Mr. Dickinson. A further clause should then be drafted, which, if necessary, the objectors might have an opportunity of discussing.

Mr. Morse pointed out that a great many tramway companies had powers of electric traction in previous Bills.

Sir Courtenay Boyle said he was considering this point. He thought the clause should be inserted in every future tramway Bill or provisional order, but he did not think the regulations ought to be scheduled in the clauses.

Mr. Morse.—How would you deal with cases of tramways which already have Bills without these clauses when they come to equip electrically?

Sir Courtenay Boyle.—I think we should recite the clauses in the regulation.

Mr. Morse.—And make the clauses and regulations applicable?

Sir Courtenay Boyle.—No; Parliament must make the clauses applicable.

Mr. Morse.—Then might I ask the Board of Trade whether they will introduce a general Bill which shall make these clauses applicable to Acts already in force where the clauses are not inserted?

Sir Courtenay Boyle said that was a very important question. If there was a sufficient desire on the part of the tramway companies at present having Acts to equip themselves electrically, then there should, he thought, be a general Act putting in these clauses. The Board of Trade would further consider the matter, but until the pressure of the companies was brought to bear on them he thought they would hardly be able to act.

The conference then terminated.

COMPANIES' MEETINGS.

LIVERPOOL ELECTRIC SUPPLY COMPANY, LIMITED.

DIRECTORS' REPORT.

The annual (eleventh) report stated that the directors were again able to announce a satisfactory increase in the number of lamps supplied from the Company's mains, the total number connected on December 31, 1893, being equivalent to 25,784 16-c.p. lamps, as against 20,254 on December 31, 1892. The balance to the credit of the profit and loss account, including £4,851. 19s. 1d. paid for interim dividend in September last, was £12,710. 16s. 6d. This sum included the balance brought forward from 1892, and the sum of £297. 8s. 7d. received for premiums and interest on share account. The directors recommended the payment of a dividend for the half-year at the rate of 5 per cent. per annum, absorbing £5,308, adding £1,000 to reserve fund, and carrying forward the balance of £1,550 to next year's account.

REVENUE ACCOUNT YEAR ENDING DEC. 31, 1893.

A.—To Generation and Distribution of Electricity.

The ordinary general meeting of this Company was held last week in the Sale-room, Exchange Station-buildings, Liverpool, Mr. A. H. Holme presiding.

The **Chairman**, in moving the adoption of the report and statement of accounts, said they proposed to pay what he hoped they would think was a good dividend. They had had a very calm and usual year. There had been the coal strike, which he thought had affected every industry in the country. The exceptionally fine weather in the autumn prevented as much light being used as had been used in previous years. Another unusual thing had been the extension of the city boundaries contemplated by the Corporation. This, he supposed, they might now consider to be almost an accomplished fact. They had made satisfactory arrangements with the Corporation, but he need not enter into them, as the change in the boundaries, although decided upon, would not come into existence until, at the very earliest, the end of this year. The Company had maintained their contract with the public, and had given them good and efficient light. They had had fewer complaints than they had ever had before, and he thought they might now say that the electric light throughout the city was as much to be relied upon as the gas was. They anticipated a large increase in the number of lights, and with that increase they would be able to charge a lower price. The increase in the number of lights had been a very satisfactory one during the past year. Their lights had been increased to the extent of over 26 per cent. There was no doubt they would have a great many more lights in future, and it would be absolutely necessary to extend their premises and provide new boilers at two stations. The rulers of the city did not seem to see their way to use the light for public purposes. He regretted that their streets and all the public buildings belonging to the Corporation were not lighted by electricity; still, he hoped that this would come in time. The expenditure on capital account during the year, including a proportionate charge for general expenses, had been £53,777. They now proposed to spend something like £29,000, and in order to do that they had issued a circular calling up the remaining 10s. per share. They continued to write off a considerable amount for depreciation, and they had put £2,000 to the renewal fund, and they had also increased the reserve fund from £2,500 to £3,500. The total depreciation they had written off since the Company commenced amounted to £26,000, which was neither too little nor too much.

The **Chairman**, in reply to Mr. James Lister, said originally the time fixed for the acquirement of the property by the Corporation was 1900, but a new arrangement had been made in connection with the city boundaries extension scheme which would give the Company an additional 42 years.

The report was seconded and adopted.

On the motion of the **Chairman**, seconded by **Mr. Ybarrando**, a dividend at the rate of 5 per cent. per annum was declared.

Messrs. Samuel H. Holme and J. C. Vaudrey were re-elected directors.

The sum of 750 guineas, free of income tax, was placed at the disposal of the directors as remuneration for their services during the past year, and a vote of thanks to the directors and to the officials of the Company concluded the proceedings.

NOTTING HILL ELECTRIC LIGHTING COMPANY.

Directors: Wm. Crookes, Esq., F.R.S., chairman; A. E. Franklin, Esq.; A. Howden, Esq.; J. T. Jervis, Esq.; F. Radford, Esq.; S. Waters, Esq. Engineer and manager, G. Schultz. Secretary, R. G. Rawkins.

Report of the directors and abstract of accounts at December 31, 1893.

The expenditure on capital account at the date of the balance-sheet amounted to £76,900. 7s. 7d. During the year a further sum of £1,628. 12s. 3d. has been so expended, bringing up the total to £78,528. 19s. 10d. The two principal items of expenditure are £744. 10s. for mains, and £522. 11s. 11d. for purchase of patents and patent rights. The result of the lawsuit between Dr. John Hopkinson and the St. James's and Pall Mall Electric Lighting Company having established the validity of the patent for the three-wire system, the property of the Westinghouse Company, we, in conjunction with the other low-tension electric lighting companies operating in London, agreed to purchase a license for the use of this system throughout our area for the full term of the patent and for any extensions thereof, the proportion paid by this Company amounting to £522. 11s. 11d. This amount has been carried to capital account under the heading above mentioned, and is only a fraction of the additional amount that would have been expended on construction had the three-wire system not been adopted. The revenue account shows a profit of £1,481. 7s. 1d., as compared with a profit of £112. 6s. 1d. in 1892, and a loss of £554. 18s. 6d. in 1891. The amount received from the sale of current shows an increase of £988. 7s. 7d., whilst the expenditure shows a decrease of £552. 14s. 8d. This result has been achieved by the abolition of the City offices, and strict economy in every detail of the work, for which great credit is due to Mr. George Schultz, the engineer and manager. It was only possible to carry these alterations into effect in the middle of the year. It is therefore estimated that a further reduction in management expenses, amounting to £280, will appear in the accounts of 1894. The directors wish to point out that the prime cost of the generation of the current during the second half of the year is lower than that appearing in any of the accounts of other London companies for 1893 hitherto published. On the occasion of the last general meeting, the directors voluntarily surrendered one-half of the fees due to them up to and inclusive of December 31, 1893, amounting to £1,125, and postponed the drawing of the balance until the present report should have been presented and approved by the shareholders. With a view of enabling the Company to start the new year free from all liability, they now surrender £685 of the balance due to them, making £1,810 in all, and accept in full payment for their services since the commencement of the Company's operations a sum of £440. The balance of net profit, after writing off the loss of £347. 16s. 4d. brought forward from the previous year's account, amounts to £1,081. 16s. 1d., and out of this the directors recommend the payment of a full dividend on the 6 per cent. preference shares, requiring a sum of £640. 19s. 4d. The Company has now been placed on a dividend-earning basis. The directors are able to report that the machinery and plant at the central station, as well as the mains, are in excellent condition, and that the supply of current during the year has given general satisfaction to the consumers. The number of houses supplied has increased from 124 to 173; and the number of lights from 9,438 to 12,153. The mains at present run past and opposite to 980 houses which are not yet taking current. The Company suffered no inconvenience through the coal strikes, as a contract had been made and a sufficient store laid down in view of possible contingencies. The Company has been in communication with the Vestry of Kensington with a view to an extension of its area in the district relinquished by the House-to-House Electric Light Company in the north-west portion of the parish, and has expressed its willingness to undertake whatever work may show a reasonable prospect of profit. The directors who retire are Messrs. Alex. Howden and J. T. Jervis, and being eligible they offer themselves for re-election. The shareholders' auditors, Messrs. Deloitte, Dever, Griffiths, and Co., retire, and do not propose to seek re-election, and the shareholders will have at the general meeting to appoint their successors. Messrs. Fox, Sissons, and Co., a member of whose firm was formerly secretary of the Company, offer themselves for the vacant post. The directors would point out that the accounts have also, under the terms of the Act, to be submitted annually to the auditors of the Board of Trade.

The annual meeting of the Company was held on Tuesday afternoon at the offices of the Company, Bulmer-place, Notting Hill-gate, Mr. William Crookes, F.R.S., occupying the chair.

The **Chairman**, in moving the adoption of the report, said that the result of the past year's working had quite reached their expectations. Referring to the accounts, as regarded No. 1 (statement of share capital), a certain portion of the capital expended in preliminary expenses was unremunerative, and not balanced by any visible asset, and this was represented by £5,500 founders' shares, leaving the rest of the capital practically represented by the visible assets of the Company. Respecting No. 2 (loan capital), the Company was free from any mortgage or debenture debt. In No. 3 (capital account), the item of £744 had been spent on making small extensions in mains to connect up houses. In most cases a satisfactory return on the capital outlay had been guaranteed. The item for patents was explained in the report, and they had a license to use the three-wire system in their area. The extra cost of construction would otherwise have been £5,000, or about 10 times as much. In No. 4 (revenue account) the cost of coal was the same as in the preceding year, the coal strike not having affected them owing to the foresight of the engineer, Mr. G. Schultz. The consumption of coal had been saved by alterations in machinery, and further economies therein would take place. It was not proposed to raise the engineer's salary of £250, but to remunerate him more in accordance with his value. The directors had decided to give him 5 per cent. on the money expended in dividends. Rates and taxes were very high, being 3s. in the pound on the net revenue owing to the high valuation on works and mains. The directors considered it should not be over one-tenth of the gross income. The directors had not drawn their full fees, and had agreed to take £440 in full discharge of arrears, amounting altogether to £2,125. The law expenses last year were only £13. 13s. The profit on the year's working amounted to £1,481, which compared most favourably with that of the previous year, when a loss of £137 would have resulted but for a fee of £250 from the New Telephone Company. The year before the actual loss was £554. The balance of profit on No. 5 (net revenue account) was £1,081, out of which was recommended a full dividend on the preference shares for the last year, being the first dividend paid. The proportion of increase of revenue was about 10 per cent. less than the increase in the number of lamps. It was estimated that, without allowing for any increase on the number of lamps at the end of last year, a net revenue of £2,500 would be obtainable this year, allowing 2½ dividend on ordinary shares at the next meeting; but, of course, further applications for light had since been received. No money had been passed to No. 7 (depreciation fund), but the directors had expended out of revenue and charged against the year's expenses £617 (equal to about 1 per cent. dividend on the ordinary shares) in renewals and reconstruction. The expiration of the lamp patent would be an inducement to householders to take current. At present their mains passed 980 houses not taking any. The number of lamps on their system had increased by 2,715 during the year. The average lamp earnings showed a tendency to sink, being only 6s. 6d. per lamp. This was probably due to the exceptional absence of fog. The Company's sheer cost per unit was lower than that shown in the accounts for 1893 of any other London company. This was the more remarkable inasmuch as the Company's output was the smallest. Now that they had turned the corner the future success of the Company was assured. Mr. Crookes then moved the adoption of the report and the payment of a full dividend on the preference shares.

Mr. Alexander Howden seconded this, and the motion was carried unanimously.

The retiring directors, Mr. Alexander Howden and Mr. J. T. Jervis, were re-elected, and Messrs. Fox, Sissons, and Co. were appointed auditors, at a fee of 30 guineas, in place of Messrs. Deloitte, Dever, Griffiths, and Co., who retired.

In reply to a question, the **Chairman** said that the Company had offered the Vestry to light the streets at cost price, but this had not been accepted. The directors, however, hoped that something might yet be done in the matter.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.

The thirtieth ordinary general meeting of this Company was held on Tuesday at the offices, Old Broad-street, Admiral Sir George H. Richards in the chair.

The **Chairman**, after alluding to the deaths of Sir G. Elliott and Captain Halpin, said that the Company had done a very good half-year's work, both as regarded cable manufacturing, the laying of cables, and other business generally. They had laid in various parts of the world cables to a distance of nearly 4,000 miles, and that very successfully. He did not see why he need allude to the causes which had produced the commercial depression of late, since the Company had been free from it. He then moved: "That the report and accounts of the directors to December, 31, 1893, submitted to the meeting be and are hereby received and adopted, and that a dividend of 36s. per share, in addition to the 12s. per share interest or interim dividend paid to June 30, 1893, be paid upon all shares of the Company for the year ending December 31, 1893, and that such dividend be paid free of income tax."

Mr. Philip Rawson, J.P., seconded the resolution, which, after some discussion, was adopted.

WATERLOO AND CITY RAILWAY COMPANY.

The first ordinary meeting of this Company was held last week at the offices, Waterloo Station, under the presidency of Mr. Wyndham Spencer Portal.

The **Chairman** said that the number of shareholders on the register was 38. His first duty was to lay on the table the Act of Incorporation empowering the Company to construct an underground railway from Waterloo to the Mansion House. This being the first meeting, there were no accounts to be submitted; but he might mention that everything was in trim for the operations of the future. As he had stated at the half-yearly meeting of the London and South-Western Railway Company, that company was deeply interested in the undertaking, which they regarded as of great value to them. It was to be a line for passengers only. It was estimated that it would be completed within two years and a half, as they anticipated no serious difficulty. In conclusion, he congratulated Mr. Scotter as the author of the scheme, as the South-Western Company had been wishing for such a line for the past 30 years.

Resolutions were adopted expressing concurrence in the issue of share capital to the amount of £500,000, with the usual borrowing powers, and in an agreement with the London and South-Western Company for the working and maintenance of the line, and for the guarantee by that company of interest on the capital at the rate of 3 per cent. in perpetuity, and two-thirds of any surplus earnings after payment of that amount, the remaining third to go to the working company.

COMPANIES' REPORTS.

CAMBRIDGE ELECTRIC SUPPLY COMPANY, LIMITED.

Directors: Rev. G. B. Finch, chairman; Hon. C. A. Parsons, managing director; Sir B. C. Browne, D. Munsey, Esq., John B. Simpson, Esq., G. Whitmore, Esq. John H. Barker, general manager and secretary.

Report of the directors to be presented to the second annual general meeting to be held at the Company's offices at Cambridge on Tuesday, March 6, at noon.

Your directors have pleasure in reporting that the prospects of the Company are satisfactory. During the last 12 months lamps equivalent to about 6,000 lamps of 10 c.p. have been connected to the Company's mains, making a total at the present time equal to 8,000 lamps of 10 c.p., and there is every prospect that the number will be largely increased during the present year. The plant during the last three months has been fairly loaded, and has worked to the satisfaction of the directors, but owing to the coal strike in the autumn a considerably increased price had to be paid for fuel. It seemed to your directors that it would be inexpedient to commence a profit and loss account in respect of supply of energy, with only a small portion of the machinery at work, and they have therefore deemed it advisable to carry all receipts and expenditure under this head up to June 30 last to capital account. The Company has made a profit of £268 to December 31 last, and it is anticipated that with the additional lamps lately connected and those which will shortly be connected, your directors will be able at the next annual meeting to advise the payment of a substantial dividend for the current year. Your directors have thought it necessary to apply to the Local Authority for their sanction to the temporary suspension of the supply of current, between the hours of 2 a.m. and 5 p.m. in summer, and 2 a m. and 6 a.m in winter. A supply during these hours would involve the shareholders in heavy additional expenditure at the present early stage of the Company's operations, with-

Digitized by Google

out any corresponding benefit to the general public. Your directors, however, hope that the applications for current will shortly be sufficient to justify them in making the supply continuous, and it will be their endeavour to effect this at the earliest opportunity. The Rev. G. B. Finch and Mr. J. B. Simpson retire by rotation; the latter is eligible and offers himself for re-election. The directors also recommend the election of Dr. P. W. Latham and Mr. W. C. Hall.

YORKSHIRE HOUSE-TO-HOUSE ELECTRICITY COMPANY, LIMITED.

Directors: Grosvenor Talbot, Southfield, Burley, Leeds, chairman; George Henry Crowther, civil engineer, Huddersfield; Robert William Eddison (John Fowler and Co., Limited, Leeds), engineer, Leeds; Robert Hudson, engineer, Gildersome Foundry, near Leeds; Samuel Ingham (Illingworth, Ingham, and Co.), timber merchant, Leeds; Arthur Greenhow Lupton (Wm. Lupton and Co.), cloth manufacturer, Leeds; John Thomas Pearson, The Hall, Melmerby, S.O., Yorkshire. Consulting electrical engineer: Robert Hammond, M.I.E.E., 117, Bishopsgate, London, E.C. Secretary: Wm. T. Green.

Report of the directors to be presented to the ordinary general meeting of the Company, to be held at the offices of the Company, Whitehall-road, Leeds, on Tuesday, March 6, 1894, at 2.30 p.m.

The directors submit herewith a statement of the income and expenditure for the past year, and the balance-sheet showing the assets and liabilities of the Company made up to December 31 last. The net profit amounts to £1,155. 6s. 1d., out of which the directors recommend that £1,000 be appropriated in reduction of the preliminary expenses account, carrying forward the balance of £155. 6s. 1d. In view of the short period during which the plant has been in use, and the fact that in respect to a large portion thereof the contractors' guarantees of maintenance had not expired on December 31, the directors do not consider it necessary at the present time to make any provision for depreciation. The absence of such necessity renders it possible to write off the above-named comparatively large sum from preliminary expenses.

The Company's permanent plant has only been at work since May 1 last, a period comprising all the summer and only half the winter months. The accompanying accounts therefore practically show results obtained during the least favourable portion of the year. The effect of the dispute in the coal trade was to add considerably to the cost of production, although the precaution was taken of securing a large stock of coal before the stoppage. Under all the circumstances the directors think the accounts now presented may be regarded as satisfactory, and they are glad to report that the supply of electricity has been maintained in such a manner as in their opinion to reflect credit upon the makers of the plant, and upon the works manager (Mr. Harold Dickinson) and the rest of the Company's staff. Almost immediately after the starting of the works it was found advisable to order an additional 200-i.h.p. engine and dynamo, which have been in satisfactory operation since the month of November. In order to obtain necessary capital, the directors invited the existing shareholders to take up the balance (2,634 shares) remaining unallotted of the first issue of 10,000 ordinary shares, and the whole of the shares have been applied for and allotted. In view of the expected early increase of demand, a further extension of the Company's works has been resolved upon, and tenders have been accepted for additional machinery of a capacity of 800 i.h.p., and for the necessary additions to the buildings, the whole to be completed and ready for next winter's lighting. The capacity of the works will thus be increased from 700 i.h.p. to 1,500 i.h.p. This extension will necessitate a small increase of capital, in addition to the amount now uncalled on part of the Company's shares, and the directors will consider how this additional capital can be raised most advantageously for the shareholders. The directors have announced that on April 1 next the standard price of electricity will be reduced from 8d. to 7d. per Board of Trade unit, subject to a scale of discounts, etc. The retiring directors, Mr. George Henry Crowther and Mr. Arthur Greenhow Lupton, being eligible, offer themselves for re-election. Mr. John Gordon, jun., offers himself for re-election as auditor.

BUSINESS NOTES.

Western and Brazilian Telegraph Company.—The receipts for the week ended February 23 were £3,181.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 25th ult. amounted to £616.

Liverpool.—The committee of the Junior Reform Club intend to introduce the electric light, at an estimated cost of installation of £1,000.

Direct Spanish Telegraph Company.—The Board recommends a dividend at the rate of 4 per cent. per annum for the half-year ended December 31.

St. Pancras.—The St. Pancras Vestry invite, by the 5th inst., tenders for Lancashire boilers, economiser, feed pumps, engines, dynamos, condensing plant, etc.

Finchley.—The School Board have instructed the clerk to write to the Education Department enquiring if a loan for the electric lighting of the schools would be sanctioned.

Dividend Warrants.—The dividend warrants on all preference shares of the City of London Electric Lighting Company, Limited, were posted to the shareholders on the 22nd ult.

Electric Time Distributing and Clock Company, Limited.—This Company has been registered, with a capital of £5,000 in £1 shares, to acquire and turn to account certain patents relating to improvements in electric clocks.

Chelsea.—The Chelsea Vestry have decided to light the town hall by electricity. Estimates have been obtained from 13 firms, varying from £225 to £500. Mr. Morgan Williams, of 39, Victoria-street, S.W., is to superintend the work.

Keighley.—The Town Council have instructed the town clerk to give the necessary notice and make application to the Board of Trade for a provisional order empowering the Corporation to lay down an installation and supply the electric light.

Bury.—The Technical School Committee of the Corporation of Bury invite tenders for the supply of electric light fittings, including switchboards, lamps, wiring, etc., for lighting the technical school. Tenders to be sent to the borough engineer by the 10th inst.

Harrogate.—The Corporation of Harrogate invite, by the 14th inst., tenders for the following plant in connection with the proposed electricity works: refuse sorting and drying plant, with accessories, steam-boilers and accessories, steam and exhaust pipes, transformers and accessories, distribution mains.

City and South London Railway.—The receipts of the Company for the week ending February 25 were £945, against £943 for the same period last year, or an increase of £2. The total receipts for the first half-year of 1894 show a decrease of £133 compared with those for the corresponding period of 1893.

Kingston-on-Thames.—The proceedings of the Electric Lighting Committee presented to the Town Council last week, recommended the acceptance of the tender of Messrs. New and Mayne for fittings for electric lighting in a portion of the market under the Town Hall for £19. 2s. The minutes of the committee were adopted.

Norwich.—At a meeting last week of the Town Council, Mr. Wild moved the acceptance of the tender of Messrs. A. Pank and Son, of Norwich, to provide and fix fittings for lighting by electricity the Guildhall, municipal, and sanitary offices for £290. 17s. This having been seconded by Mr. Dakin, was after some discussion adopted.

Dissolution of Partnership.—The firm of Charlesworth, Hall, and Co., of Oldham, has been dissolved. Mr. Joseph Platt Hall has purchased Mr. Charlesworth's interest in the property and assets of the company, and will carry on business as electrical engineer at Blackriding Ironworks, Oldham, under the style of J. P. Hall and Co.

Blackpool Tower Buildings.—The contract for the electric lighting of the Blackpool Tower buildings has been let to Messrs. Verity and Sons and Messrs. Siemens, the amount of their estimate being £6,092. 10s. The contract for plastering at the same buildings has been let to Messrs. T. and S. Wardle, of Manchester, their estimate being £2,260.

Leeds.—The directors of the Yorkshire House-to-House Electricity Company, Limited, have decided to let the contracts for the extension of the electricity works as follows: to Messrs. William Nicholson and Son, for the buildings; and to Messrs. Hick, Hargreaves, and Co., Limited, and Messrs. John Fowler and Co. (Leeds), Limited, for the plant.

Acton.—The Works Committee to the Local Board last week reported that, after making some slight alterations, they had instructed the clerk to return to Mr. Medhurst the agreement as to the electric lighting of the district. The committee added that if Mr. Medhurst accepted these alterations, the conditions of lease and the schedule could be reconsidered.

Wigan.—At a meeting of the Gas Committee last week, it was resolved that the committee proceed with the erection of electric lighting works, and that in the event of the resolution meeting with the approval of the Council a meeting of the committee be called for Friday, March 9, to consider the question of the appointment of an electrical engineer to advise the committee.

Water-Tube Boilers.—Messrs. R. Hornsby and Sons, Limited, of Spittlegate Ironworks, Grantham, are manufacturing a large double-furnace water-tube boiler for the Whitehead Torpedo Company, at Weymouth, being the third order given by them for this type of boiler. We understand from the purchasers that the economy of fuel in the working of these boilers is quite beyond their expectations.

Aberdeen.—Mr. Wm. Smith, harbour engineer, is preparing a modified scheme on the lines of Mr. Copland's proposal for the improvement of Regent Bridge. It is now proposed to have a travelling bridge in place of a swinging bridge, the roadway rising and falling as the bridge opens and closes. The motive power for the opening and shutting of the bridge will be electricity; and the estimated cost is £6,000.

Mansion-Lighting at Ilkley.—Messrs. Andrews and Preece, of Bradford, have secured the contract for the electric light installation for the mansion now being erected at Ilkley by Mr. W. Smith. The motive power will be supplied from one of Messrs. Gilkes's vortex turbines. The specification has been prepared by and the work is in charge of Mr. Edwin Blakey, M.I.E.E., consulting engineer, of Tanfield-chambers, Bradford.

The Maxim-Nordenfelt Company.—Admiral of the Fleet Sir Edmund Commerell, chairman of the Maxim-Nordenfelt Guns and Ammunition Company, Limited, mentioned last week that the company had taken up electricity as a branch, and that they found that their workmen could do this sort of work quite as well as they could make Maxim guns. They considered that electricity offered an excellent field for employment in the future.

Electric Cranes.—Messrs. J. G. Statter and Co., Limited, of Princes-mansions, 68, Victoria-street, S.W., inform us that, following the completion of the electric cranes erected by them for the Southampton Harbour Board and those for the London and India Docks Joint Committee, they have received an order from the South-Western Railway Company of Russia for three electric cranes and generating station for the harbour at Odessa.

Islington.—The vestry clerk read a communication last week from the London County Council stating that they were prepared to grant a loan of £9,000 for the purpose of purchasing a site for an electric lighting station, at the rate of £3. 10s per cent. per annum, calculated quarterly by equal half-yearly instalments of principal and interest combined for 55 years, the Vestry to pay the cost of the loan. The letter was referred to the Electric Lighting Committee.

Edinburgh.—The Corporation of Edinburgh invite tenders, by the 17th inst., for the following work in connection with the electric lighting of the city: Contract No. 5, construction of concrete culverts and laying of stoneware and iron pipes and casings; No. 6, supply of cast-iron pipes, casings, and road service boxes; No. 7, supply of stoneware casings and insulators; No. 8, supply of copper strip; No. 9, supply of armoured and unarmoured insulated cable.

Bournemouth.—At a meeting of the Town Council last week the Lighting Committee reported a letter from the Town's Interest Association, asking whether the time had not arrived for lighting the borough with electricity. The committee recommended that a reply be given to the effect that the Council were not prepared to consider the question at present. The report was adopted. The report of Major Cardew with reference to the recent accident was received and referred to the Lighting Committee.

Newark.—At a meeting last week of the Sanitary Authority the Electric Lighting Committee reported that they had had before them an application from Mr. Norledge, solicitor, asking their sanction to a company obtaining a provisional order to supply the town with the electric light, and they had decided to leave the question open for the opinion of the Authority. The Mayor proposed that the application be not granted. Mr. Shepherd seconded the resolution, which was carried.

The Effect of Lightning upon Trees.—With reference to the note on this subject in our last issue, Messrs. S. Burnley and Son, of 121, Coldharbour-lane, Denmark Hill, S.E., write to us as follows: "Last March a cherry tree was supported by being fastened round the centre with a stout, solid iron wire to a poplar tree about 30ft. apart, and during the summer gave plenty of fruit, but in September was struck by lightning, supposed by the wire from the poplar tree. The poplar tree is not affected, but the cherry tree is quite dead, as can be seen."

New Installation at Liverpool.—Messrs. Bennett and Druce, 44, Fishergate, Preston, have been entrusted by Messrs. Frisby, Dyke, and Co., of Liverpool, with the complete lighting of their premises by electricity. The plant will consist of an "Otto" gas-engine, giving 22 h.p. on the brake, a compound-wound dynamo, and about 250 lamps distributed over the shop and premises to the entire exclusion of gas. Provision is to be made

Digitized by Google

for taking current from the supply company's mains in case a few lights are required during the daytime.

Church-Lighting.—Mr. C. W. Watling, of 110, New-road, Dearnley, Rochdale, informs us that an installation of the electric light has been made in the new church of St. Andrew, Dearnley, a suburb of Rochdale. The work of installing the light has been carried out by Mr. James Wilcock, electrical engineer, of Littleborough, near Manchester, to the satisfaction of the Building Committee. The church is lighted by 60 100-volt incandescent lamps, the dynamo being driven by a 4-h.p. nominal Crossley gas-engine.

Lighting of Sir Thomas Lucas's House.—This work is now nearing completion, and the contractors, Messrs. Drake and Gorham, have dealt in a satisfactory manner with the difficulties which presented themselves at every turn. Sir Thomas was naturally desirous that the splendid decorations should not be interfered with in any way, and before the contract was given full enquiries were made as to how similar work had been dealt with, which had proved eminently satisfactory. Another source of difficulty was the solid construction of the building, and no cutting away was allowed, a positive assurance being given to Sir Thomas Lucas to that effect. There are 370 lights.

Electrically-Lighted Omnibuses.—The Omnibus and Tramcar Electric Lighting Company have acquired the license for the patent that has been tested for two years on the Paris, Lyons, and Mediterranean Railway, and the Liège and Maestricht Railway with satisfactory results. For the new battery invented by Messrs. Theryc and Oblasser it is claimed that the problem of lighting road vehicles has been solved. On Saturday, at the offices of the Omnibus and Tramcar Electric Lighting Company, 18, Eldon-street, E.C., there was a demonstration of the capabilities of the new system. It is proposed that each omnibus should carry a lamp provided with a special bullseye reflector, and yielding light equal to that of 2½ candles. A battery weighing 30lb. will, it is said, furnish a light of 2½ c.p. for 45 to 55 hours.

A Petroleum Question.—The India Rubber, Gutta Percha, and Telegraph Company, of Silvertown, were last week summoned for keeping at their Birmingham branch a solution which, within the meaning of the Act, was petroleum, without obtaining a license. Over 1,000 cans of liquid seized were found to contain a solution of rubber and naphtha, the proportion of naphtha being 84·8 per cent. The solution gave off vapour of 58deg. F., being less than 78deg., as required by the Act. It was argued, in defence, that the solution was not petroleum in the meaning of the Act, and that the Act was intended to apply to fine petroleum, and not to admixture with other substances for commercial purposes. It was extensively used in the manufacture of tyres and bicycles, and defendants were not aware that they were under any legal obligation. A fine of 40s. and costs was imposed.

Electric Lighting of Paperworks.—The extensions which have from time to time been carried out at the Ulverston Paperworks by Messrs. S. Pollitt and Co. have been succeeded by the substitution of the electric light for gas, and this system of illumination was last week successfully inaugurated. The installation, which was contracted for and completed by Messrs. W. R. Thornton and Son, electrical engineers, of Duke-street, Barrow, under the personal management of the junior partner of the firm, consists of a vertical steam-engine driving a dynamo by means of a leather link belt, and the total number of lights provided for is equal to 500 lamps of 8 c.p. The engine is of about 30 i.h.p., and it runs at 190 revolutions per minute. The dynamo is compound wound. The distributing switchboard divides the installation into eight separate circuits, comprising offices, machine-room, sorting-room, beating-room, engines, and boilers, rag-boiler, joiners' shop, and bagmaking-room.

Portsmouth.—Mr. E. Manville has written as follows to Mr. George Ellis, Landguard, Southsea: "Referring to the statements that I understand have been published in the Portsmouth papers with relation to the accident to a horse at Bournemouth, I wish to point out to you that it is impossible such an accident could happen at Portsmouth through the electric light mains there. According to Major Cardew's report to the Board of Trade, the high-tension electric light mains at Bournemouth consisted of two separate cables, both of which were insulated, or rather attempted to be insulated, from the earth. In your case the high-tension conductors consist of two concentric conductors, one without the other, and the outer one is placed in good connection with the earth. It therefore follows that it is impossible that anything can come in contact with the inner or live conductor. In addition, those precautions which Major Cardew stated would have prevented any accident occurring at Bournemouth had they been adopted there, have been already provided for in your system."

Keswick.—The annual report of the Keswick Electric Light Company has just been issued, in which the directors state their inability to recommend a dividend, but are obliged to declare a loss on the past year's business of £69. 5s. 7d. The use of steam instead of water (which the directors have been unable to avoid) is of itself sufficient to account for loss of profit, but the directors have now confident expectations of being able very soon to use the whole water power of the river, without which success is impossible. The trade of the past year shows an increase of 51 lamps, representing £66. 9s. 3d. in receipts. There appears to be a decided disposition in the neighbourhood for people to avail themselves of the light, but as the output is restricted the directors cannot push business as they would like to do. Were ample machinery supplied for procuring the current, they feel confident of a fairly satisfactory result. To obtain this result it will be necessary to procure more capital. Considerable additions to and alterations in plant, wiring, etc., will be necessary to work an increased and remunerative trade, which cannot be expected from the present small station. The directors therefore trust that when their plans for enlargement of the station have been prepared and laid before the shareholders, a ready response will be made, and the necessary additional capital subscribed. The directors have thought it necessary in the interests of the company to procure from a professional electrical engineer a full report upon the station and works, and suggestions as to the alterations and additions required to make the undertaking a success.

The Windsor Electric Lighting Difficulty.—At the Windsor Police Court last week Mr. A. E. Farrow, engineer to Messrs. Roger Dawson, Limited, of London and Windsor, was charged with having broken up the High-street without having first obtained the consent of the Town Council, acting as the urban sanitary authority for New Windsor, as required by the Public Health Act, 1875, sec. 149. Mr. G. H. Long, town clerk, appeared for the Sanitary Authority. The defendant was unrepresented. It transpired that at half-past ten on the night of January 2, the workmen, acting under instructions from the defendant cut a trench 39ft. to 40ft. long and 9in. wide across the High-street, in order to lay down electric lighting wires. The superficial area disturbed was put by the borough surveyor at 46ft. 3in. The defendant pleaded guilty to having instructed the workmen to make this trench, and he explained that he had not asked for permission because he had been told by Mr. Sevenoaks that he would not be likely to get it, and he was advised to take up the street without permission, as was done on a former occasion, when wires were laid across Peascod-street to a Mr. Badger's shop. The Town Clerk stated that permission for such work, when properly asked for, was never refused. He also said that the Town Council had given him no instructions to proceed in Badger's case. The chairman (Mr. G. H. Peters) observed that it could never be tolerated that anybody could come into Windsor and pull up the roads and paths, and set the authorities at defiance. The Bench did not desire to deal harshly with the defendant, but he would have to pay a fine of £2, and a penalty of 3d. per square foot, and costs £1, making altogether £3. 10s. The money was paid at once. The statute provides a penalty not exceeding £5, and a further penalty not exceeding 5s. per square foot.

Hanley Electricity Works.—The Town Council obtained a provisional order in 1891, and in September, 1892, the Council accepted the tender, amounting to £15,760, of the Brush Electrical Engineering Company for the boilers, engines, dynamos, mains, and sub-station transformers requisite for dealing with the compulsory area lighting, both public and private, in its first stages. The Board of Trade approved of the system adopted for the supply of electrical energy, subject to the regulations and conditions for securing the safety of the public, and for ensuring a proper and efficient supply imposed upon the undertakers by the provisional order. The system adopted is the high-pressure alternating current method, with transformers at sub-stations, from which low-pressure distributing mains are to be laid to consumers' premises. The sanction of the Board of Trade to the scheme having been obtained, the Local Government Board, after enquiry, consented to the Council borrowing the sum of £21,000, repayable in 25 years, for the purposes of the order. A contract was soon afterwards entered into with Mr. C. Cornes for the erection of the requisite buildings at the generating station. The electric works are situated on land belonging to the Park estate, and near to Messrs. Hampton's brickworks, on the south side of Clifford-street. The present plant consists of two 100-i.h.p. vertical compound engines, each driving by means of ropes a 50-kilowatt alternator; two 200-i.h.p. engines of the same kind, each driving a 100-kilowatt alternator. A dynamo capable of producing the exciting continuous current required for all the alternators will be driven by the power derived from each of the first-named engines. Space remains for the erection of another 200-h.p. engine and 100-kilowatt alternator when required. There is a smaller engine-room, affording room for two compound vertical engines of 20 h.p. each, and two dynamos, each being capable of furnishing continuous current for 30 arc lamps for public street lighting. One engine and dynamo will therefore be in reserve, and when another set of arc lamps are required it will only be necessary to provide one additional engine and dynamo. The boiler-house floor is 9ft. below main engine-room floor. Three Lancashire boilers, each 7ft. diameter, 28ft. long, with Galloway tubes, provide steam at a pressure of 120lb. One boiler will always be in reserve. The Corporation have laid mains for the supply of electricity in various streets. Mr. Joseph Lobley is the borough engineer and surveyor, and he has had the superintendence, assisted by Mr. G. H. Cottam, electrical engineer, of the undertaking.

An Action about Shares.—In the Lord Mayor's Court last week, before the Recorder (Sir Charles Hall, Q.C., M.P.), and a special jury, the case of M'Carthy *v.* the Electric Construction Company, Limited, came on for trial. It was a claim by the plaintiff to recover the sum of £2,600, being the proceeds of the sale of 605 shares in the defendant company by whom the plaintiff was formerly employed as clerk and book-keeper. Mr. Pyke, Q.C., and Mr. Edward Turner appeared for the plaintiff, and Mr. Kemp, Q.C., and Mr. Reginald Brown represented the defendants. In opening the plaintiff's case, counsel stated that the proceeds of the shares in question had been received by the defendant corporation. The Electric Construction Corporation was founded, promoted, and formed in the year 1889, at the instance of the Building Society Securities Corporation, at the head of

Digitized by Google

which was Mr. Jabez Spencer Balfour. Mr. Balfour was a director, and the shareholders included Captain Dibley, Henry Granville Wright, Hobbs, and Newman, all of whom became shareholders in the Electric Construction Corporation, and some of whom were directors of both companies. In 1889 there were allotted to Captain Dibley 1,712 £10 shares in the corporation which purported to be fully paid up. Five hundred of these shares were transferred to the plaintiff for the sum of 5s Those shares were sold within a few weeks by the defendant corporation for the sum of £2,234. 7s. 6d. The sum was paid by a cheque drawn to M'Carthy or bearer, and was paid by the corporation into their bank. The plaintiff's case was that, having taken the risk attaching to those shares, he was entitled to the sum which they realised. The suggestion of the defendants was that the shares were put into the hands of the plaintiff for sale as the trustee of the corporation, but counsel contended that there was no defence in law as the corporation had no power whatever to deal in its own shares. The plaintiff, as the holder of the certificate, was the legal owner of the shares and entitled to the proceeds of the shares. On November 14, 105 more shares were transferred to Mr. M'Carthy in the same way, and the proceeds of those shares, amounting to £414, were kept by the corporation, they having been sold, and these sums together made up the plaintiff's claim. After the plaintiff had given his evidence, it was submitted on behalf of the defendants that there was no case to go to the jury. After hearing the address of counsel, the jury intimated that they had made up their minds and a verdict was taken for the defendants.

PROVISIONAL PATENTS, 1894.

FEBRUARY 19.

3519. **Improvements in chairs and rails for electric tramways underground channel.** John Wilkinson, 27, Rawcliffe-street, South Shore, Blackpool.

3545. **An electrically-controlled race game.** George Gladman Sarney, 145, Mayall-road, Herne Hill, London.

3548. **Improvements in and relating to electric arc lamps, and mechanism for operating and controlling the same.** Walter Rowbotham, Tintern Lodge, Upper Chorlton-road, Whalley Range, Manchester.

FEBRUARY 20.

3589. **Improvements in electric arc lamps.** Richard Alfred Goodman and Arthur Bernoullé Barlow, 17, St. Ann's-square, Manchester.

3609. **Improvements in mechanical and electrical interlocking in connection with railway signalling.** William Henry Elliott, Railway Cottage, Thurles, co. Tipperary.

3641. **Improvements in ships' telegraph and indicating apparatus.** Thomas Mudd, 6, Lord-street, Liverpool.

3652. **Improvements in the arrangements for working railway signals electrically.** Illius Augustus Timmis, 2, Great George-street, Westminster.

3658. **Improvement in dynamo-electric machines.** Charles James Hall, 433, Strand, London. (Complete specification.)

3667. **Improvements in telegraphic and telephonic apparatus.** The Phonopore Company, Limited, and Edward Wythe Smith, 28, Southampton-buildings, Chancery-lane, London.

3674. **Improvements in primary galvanic batteries and in the liquids used therein.** William Heaton Longsdorf, 73, Cheapside, London. (Gardner Hewett, United States.)

3688. **The electric light cane.** Augustus Hamilton Johnston, 22, Draycott-place, Cadogan-gardens, Sloane-square, London.

FEBRUARY 21.

3725. **Dry or semi-dry galvanic elements.** Thomas Blackhurst, 31, London-terrace, Darwen, Lancs.

3729. **Improvements in dynamo-electric machines.** Ernest Alexander Claremont, 53, Arcade-chambers, St. Mary's-gate, Manchester. (Complete specification.)

3730. **Improvements in electric arc lamps.** Ernest Alexander Claremont, 53, Arcade-chambers, St. Mary's-gate, Manchester. (Complete specification.)

3749. **Improvements in galvanic batteries.** Alfred Julius Boult, 323, High Holborn, London. (Carl Cudell, Iwan Cudell, and Max Cudell, Germany.) (Complete specification.)

FEBRUARY 22.

3841. **Improvements in electric motors for vehicles.** Charles Edward Grove, 28, Southampton-buildings, Chancery-lane, London.

3859. **Improvements in or relating to electric gas-lighting apparatus.** William Phillips Thompson, 6, Lord-street, Liverpool. (Milton Ulmer, Germany.)

3860. **Improvements in dynamo-electric machines.** Alexander Linard, 323, High Holborn, London.

3863. **An improved electric arc lamp.** A. E. Jones, 45, Southampton-buildings, Chancery-lane, London.

FEBRUARY 23.

3897. **An improved bracket for telegraph or other insulators.** William John Hancock, 15, Victoria-street, Westminster.

3902. **A new method of applying electromotors to lathe work.** Arthur Chamberlain and George Hookham, 18, Southampton-buildings, Chancery-lane, London. (Complete specification.)

3922. **Improvements in or relating to the electro-decomposition of metals.** Margaret Roskell, 6 Lord-street, Liverpool.

3926. **Improvements in or applicable to dynamo-electric and other machines or apparatus for the purpose of preventing or retarding the passage of magnetic lines of force from or to such machines or apparatus.** William Morris Mordey, 46, Lincoln's-inn-fields, London.

3931. **Improvements in apparatus for transforming continuous electric currents into alternating currents.** Franz Severin Ferdinand Schneider, 45, Southampton-buildings, Chancery-lane, London.

FEBRUARY 24.

3951. **Improvements in dynamo-electric machines.** Frank Richmond, 79, St. James-street, Burnley.

3962. **Improvements in electrical switches.** Charles Mark Dorman and Reginald Arthur Smith, Ordsal Electrical Works, Salford, Manchester. (Complete specification.)

3976. **A method of utilising the movements of the recorder coil or siphon connected thereto, or the movements of other apparatus used for receiving telegraphic messages through submarine cables or land-lines to automatically transmit telegraphic messages from one submarine cable or land-line to another submarine cable or land-line.** John Boyes, 50, Old Broad-street, London.

3986. **Improvements in electric motors.** William Phillips Thompson, 6, Lord-street, Liverpool. (The Ries Electric Speciality Company, United States.) (Complete specification.)

4921. **Improvements in telephone transmitters and arrangements for same.** Alfred Charles Brown, 129, Algernon-road, Lewisham, London.

SPECIFICATIONS PUBLISHED.

1890.

2296. **Electrolytic production of caustic soda, etc.** Richardson and Holland. (Amended specification.)

1892.

10200. **Electro-chemical production of bleaching agents.** Kellner. (Second edition.)

19714. **Dynamo-electric machines.** Chitty.

23023. **Telephonic news transmitters.** Puskas.

1893.

36. **Electrical station indicators for vehicles.** Villiers-Stead.

2922. **Electric clocks.** Scott and Burnet.

3413. **Telegraph recording instruments.** Muirhead and Edgar.

3690. **Ammeter and voltmeter.** Morris.

4952. **Electrical relays and measuring instruments.** Smith and Granville.

5337. **Conductors for electric railways.** Ewing.

5505. **Moulding bodies of electric switches, etc.** Watkin.

5733. **Reading deflections of reflecting instruments.** Baron Kelvin.

6813. **Electric arc lamps.** Bryan.

6933. **Working railway signals.** Automatic Electric Railway Signal Company and Blakey.

6965. **Electric furnaces.** Urbanitzky and Fellner.

9478. **Insulators for electric wires.** Lake. (Hartmann and Braun.)

10147. **Applying electricity to human body.** Dowling.

19967. **Secondary batteries.** Petschel.

22858. **Electric lighting and extinguishing apparatus for gas burners.** Orling.

24946. **Coverings for electric wires.** Randall and others.

24948 **Time electric switch.** De Segundo and Derham.

NOTES.

Rangoon.—It is intended to light the new Government house at Rangoon by electricity.

A Good Example.—The Chelmsford Gas Company desire to be on good terms with the local electric light company.

Lecture.—Before the Royal Institution of South Wales last week, Mr. Alex. Sinclair, A.M.I.E.E., delivered a lecture on "Submarine Telegraphy."

Sanction of Loan.—The Treasury has sanctioned a loan of £9,000 by the London County Council to the Vestry of Islington for the purchase of a site for electric light works.

Smoking Concert.—A successful smoking concert was given last Friday by the employés of Messrs. Drake and Gorham, when about 130 of the London staff listened to an excellent programme.

Description of Works.—The *British and Colonial Printer* of March 1 contains an illustrated description of the electrical engineering works of Messrs. Ernest Scott and Mountain, Limited, at Newcastle.

Visit to Works.—The members of the Leeds Association of Engineers recently visited the works of the Yorkshire House-to-House Electricity Company, in Leeds. Mr. R. W. Eddison conducted the visitors round the station.

Thames Embankment.—The Highways Committee of the London County Council on Tuesday again recommended the carrying out of the electric lighting of the Victoria Embankment. The matter was, however, postponed.

An Electrical Inspector.—The City Commission of Sewers, on the recommendation of the Streets Committee, resolved on Tuesday to appoint an electrical inspector under the Electric Lighting Act at a salary of £250 per annum.

French Electric Locomotives.—Persons travelling to Nice will, a Paris correspondent says, shortly see the new electric locomotives which the Paris-Lyons Company is building at the Oullins works, near Lyons, for its fast express traffic.

Students of the Institution.—A students' meeting of the Institution of Electrical Engineers will be held on Friday next, the 16th inst., at 28, Victoria-street, S.W. A paper will be read on "The Construction of Resistances" by Mr. D. K. Morris.

Junior Engineering Society.—As stated in our last issue, a paper will be read before this society this (Friday) evening on "The Design, Construction, and Working of Boilers for Locomotive Engines," by Mr. G. Frank Burtt, G.I.Mech.E., member.

Rectifiers.—A passage of arms is taking place between Mr. Massey and Mr. Sydney F. Walker, in one of the South Wales newspapers, concerning the merits or otherwise of the rectifiers proposed to be introduced in Cardiff, and the system of mains adopted there by Mr. Massey.

Bethnal Green.—Mr. T. H. Rippin expressed the hope on Wednesday evening, at a meeting convened to protest against the charge by the Gaslight and Coke Company of 3s. 1d. per thousand for gas, that the Bethnal Green Vestry would take in hand the subject of introducing the electric light.

St. Pancras.—The Vestry have declined to accept the terms of the London County Council for a loan for electric lighting purposes for the period of 25 years. They have decided to borrow from the Prudential Company at the same rate, and for the original period of 42 years.

A Bicycle Electric Railway.—A railway on the bicycle system, devised by Mr. Boynton, is now in process of erection across Long Island, from Bellport to the Sound. The idea of the bicycle railway is to provide a system of transit whose speed may be from 75 to 100 or more miles an hour.

Lighting of Londonderry.—Mr. Charles P. Cotton, M.I.C.E., engineering inspector under the Local Government Board, has held an enquiry in connection with the application by the Corporation of Londonderry for sanction to a supplemental loan of £5,000 to complete the electric lighting works.

Castle-Lighting.—Prince Bismarck's castle at Friedrichsruhe has been recently lighted by electricity, the power being derived from some sawmills which belong to the Prince, situated within a short distance of the castle. The Elektrizitäts-Gesellschaft, of Hamburg, formerly known as Schuckert and Co., carried out the installation.

Coventry Electric Tramway.—It is reported that arrangements are now completed for the commencement in two or three weeks of work on the tramways, and that it is expected the cars will begin running in the summer. The electric cars will run to Bedworth, a distance of over five miles, with a 10 minutes' service to and from Longford.

Telephony.—During an experiment with the telephone between Trieste and Berlin the other day, the official in Berlin began by singing an air from the operetta "Die Vogelhändler," and the one at Trieste answered by an air from "Cavelleria Rusticana." It was noticed that the singing was heard perfectly, while mere speech was confused and indistinct.

Engineering Works near Wolverhampton.—Rumour is again current that arrangements have been completed for the erection and equipment of works on a large scale, near Wolverhampton, for the manufacture of dynamos and other electrical apparatus. The establishment will, it is said, be the property of a joint-stock company now in process of formation.

Scarborough.—The Mayor of Scarborough (Mr. G. L. Beeforth, J.P.) was "At Home" on Wednesday of last week at the Grand Hotel, and received over six hundred ladies and gentlemen in the banqueting hall. The Scarborough Electric Supply Company gave an exhibition of electrical appliances. Mr. A. A. Campbell Swinton, the managing director of the company, conducted a series of experiments.

Institution of Civil Engineers.—On Tuesday next, the 13th inst., the following papers will be further discussed: "The Liverpool Overhead Railway," by Messrs. J. H. Greathead and Francis Fox, MM.I.C.E.; and "The Electrical Equipment of the Liverpool Overhead Railway," by Mr. Thomas Parker, M.I.C.E. If time permits, a paper will be read on "The Prevention and Detection of Waste of Water," by Mr. Ernest Collins, M.I.C.E.

Telephony between Berlin and Copenhagen.—The first step has been taken towards the establishment of telephonic communication between Copenhagen and Berlin. The Finance Committee of the Folksthing has reported in favour of the proposal of the German Telegraph Department that the cable between Copenhagen and Odensce shall be so laid as to form a part of the eventual telephone line to be carried *vid* Odenser, Kolding, and Hamburg, to Berlin.

Northern Society of Electrical Engineers.—An ordinary general meeting of this society will be held on Monday next, the 12th inst., at the Palatine Hotel, Hunt's Bank, Manchester, commencing at 8 p.m. Mr. John H. Rider is announced to read a paper, entitled "Notes on

Digitized by Google

Designing a System of Underground Electric Light Mains," whilst Mr. S. V. Clirehugh will present a paper on "The Various Systems of Underground Mains and Methods of Laying Same."

Newcastle.—The Mayor, in referring to the tramways at the annual dinner a few days ago of the Newcastle Association of Students in connection with the Institution of Civil Engineers, said that it was quite possible that in eight or ten years the electric system might be found superior to the cable system. It was necessary therefore, he observed, to move with caution before making the change recommended by a committee of the Town Council for the substitution of the cable system for horse haulage.

Combined Telephone and Telegraph System.—A telegram from Berlin states that a Russian inventor, M. Gwozdef, claims the discovery of a new telephone ystem whereby spoken messages can be transmitted over very great distances wherever an ordinary telegraph line is aid, and without in any way interfering with the telegraphic despatches. As M. Gwozdef considers his invention invaluable in case of war or sudden mobilisation, he has resigned all claims to it in favour of the Russian Government.

The Douglas Tramway.—With reference to the note on this subject in our last issue, we observe that the Isle of Man Tramway Company have now decided to sell their undertaking to the Douglas and Laxey Electric Tramway Company for £38,000. It would be interesting to learn who are the shareholders in the latter, and who should understand, even if they do not, that the tramway system can be acquired by the Douglas Commissioners in four years hence for £25,000. It is a pity for money to be, as it appears, thrown away in this manner.

The Kinetoscope.—A telegram from New York on Wednesday announces that Mr. Edison has now perfected his kinetoscope for the continuous photography of objects in motion. By means of this invention it is said that he can take a number of impressions by means of a camera in a very limited space of time, thus obtaining a continuous photograph of the entire motion of the object or person selected. The photographs follow each other in such rapid succession that no lapse of time can be detected between the impressions recorded, and the series becomes in effect but one picture.

Projected Electric Railway in Denmark.—An application, according to *Engineering*, has been made to the Danish Government for a concession for an electric railway from Klampenborg to Humlebök, both on the Sound, a distance of some 16 miles. The plan does not include any contribution from the State, nor from the districts through which it will have to pass. It is principally intended for passenger traffic, only secondarily for goods. The Danish Government has proposed a railway from Klampenborg to Elsinore, which would entail an expenditure of some £350,000, whilst the proposed electric railway will not cost the State anything, in addition to which the Parliament does not seem disposed to pass the Government's Bill.

Chelsea Company's Preference Shares.—As notified in our advertisement columns, the Electric and General Investment Company, Limited, of 1 and 2, Great Winchester-street, E.C., invite subscriptions for 6,000 6 per cent. preference shares of £5 each in the Chelsea Electricity Supply Company, Limited. The shares, which are offered at a premium of 10s. per share, will be entitled to be paid yearly out of the profits a preferential dividend at the rate of 6 per cent. per annum. The nominal capital of the company, of which £88,785 is paid up, is £100,500, and the additional capital now sought is required for the extension of mains into a fresh district in Chelsea, and to defray the cost of the buildings, works, and machinery necessary to enable the company to cope with the increasing demand for current. The lists of subscriptions opened on Tuesday, the 6th inst., and will close for both town and country on Tuesday next, the 13th inst.

The Konigsberg Electricity Works.—This station is one which is of considerable interest among German stations, and is remarkable chiefly for two features: its circuits are on the five-wire system, and the mains are laid in conduits. The engines are of triple-expansion vertical type, and by Schichau, of Elbing; there are two of 200 h.p. and two of 100 h.p.: they run at 200 revolutions a minute, and are directly coupled each to two multipolar dynamos, which have the outside wires of their disc armatures arranged as commutators. Very full descriptions are given in the columns of a German electrical journal of the circuits of the five-wire supply, and also of the conduit in which the five conductors of bare copper strip are carried on insulators of the telegraph type. These mains are calculated for 60,000 lamps, but the present station can only supply 16,000. All details given are very full, and the financial results, in spite of the disproportionately heavy outlay on mains, are stated to be satisfactory.

A Phenomenon of Electromagnetic Rotation. In a recent issue of the *Elektrotechnische Zeitschrift*, Mr. M. Jüllig referred to a phenomenon of this character. He states that if a hollow copper ball be suspended by a thread in the field of an electromagnet the coils of which are traversed by an alternating current, a turning moment is generally produced in the ball, causing it to rotate. This rotation, however, does not take place (1) if the centre of the ball lies in the plane at right angles to the plane of the magnet and to the line joining its poles; (2) if the centre of the ball lies in the plane of the magnet. In every other position the ball rotates without being artificially started; but it is necessary to work with large forces, as the rotation is due to a small difference of impulses. A diagram of the poles and ball in plan will show that each pole makes an induced current in the sphere, and the resultant current is more strongly acted on by one pole than by the other. The phenomenon might possibly be used in the construction of an ampere-hour meter for use with alternating currents.

Some Notes on Brush Discharges in Gases.—A remarkable difference between the behaviour of positive and negative electricity in high-frequency discharges, which was observed by Messrs. W. H. Harvey and F. Bird, forms the subject of a note by them in the *Philosophical Magazine*. The arrangement of apparatus is as follows: A small magneto excites the primary of an induction coil whose secondary can give about an inch spark with eight volts on the primary. The terminals of the secondary are connected to two condensers of similar capacity, about $38/10^4$ microfarad, and also to the two balls of a spark-gap. The other coatings of the condensers are connected through the primary of an air transformer, whose secondary is utilised to produce high-potential and high-frequency brush discharges. The discharges, which were always vivid, were most brilliant when allowed to take place between a point and a plate having some capacity, and this plate had always a positive charge, though the discharge was of course oscillatory. The details of the experiment were varied in every way, but the plate always remained positive. If either end of the transformer secondary were connected to the plate, and the other end immersed in oil, the result was always the same—a strong positive charge. If the

Digitized by Google

discharge was made to take place in dry hydrogen, the reverse result was obtained, the charge being negative. It appeared probable that a negative charge passes more easily in hydrogen than a positive. Oxygen behaved like air, the charge on the plate being positive. These results have been to some extent anticipated, Guthrie having shown that a red-hot conductor in air retains a negative, but not a positive, charge.

Multiple Switchboards for Telephony. — The general interest manifested both by practical men and the public in the development of telephony may have inspired the late director of the German Government telephone service, Mr. J. Sack, to write a pamphlet, which we now have before us. It is entitled "Telephonbetrieb mit Klappenschranken mit Vielfachumschalter," and is published by Messrs. F. A. Gunther and Sohn, of Berlin, at the price of one shilling. The author has been connected with the general management of the German Government telephone exchange service almost since it was established, and in comparing the three systems of multiple switchboards now in use at the leading telephone exchanges in the world, he concludes in favour of the latest invention, which has been in successful operation for the last 12 months in the German telephone exchanges. Mr. Sack compares the system of Scribner, Kellogg, and of Mix and Genest, illustrating each system by means of diagrams, and fully describing advantages and disadvantages of each system. Although written in German, we have no doubt that telephone engineers without any knowledge of that language will be able to gather sufficient information from the diagrams. The author decides in favour of the multiple switchboard constructed by Messrs. Mix and Genest on account of the impossibility of delays on the part of the operator at the exchange. The separate test line is entirely dispensed with, and the operator need not strain her ear as she tests with the galvanometer, thus relieving the operator physically. The disconnection of two subscribers during a pause, which is not an unfrequent occurrence, cannot take place in this system of testing the line. The pamphlet is well written and printed, and can be recommended to those interested in telephony.

The Phonograph and Microphone in Medical Studies.—At the conversazione held recently in Glasgow, Dr. Macintyre exhibited a number of new electrical instruments, as well as some interesting micro-phonographic records. With the perfection to which the instrument has now been brought, says *Industries*, the phonograph is not unlikely soon to take its place as an instrument of instruction in medical teaching. Dr. Macintyre was able to demonstrate a number of cough sounds and varieties of hoarseness due to different pathological conditions; and he has been able by special recording arrangements to register the heart sounds. Doubtless, stethoscopic sounds offer the greatest difficulty of all, but by properly arranged conducting apparatus fairly good records have been obtained of different sounds heard within the chest. Dr. Macintyre also exhibited a number of microphones—some of the ordinary varieties and others adapted specially for medical purposes. The principal one of interest was an instrument enabling a number of students to listen to the sounds of the body at the same time, and also to transmit these sounds to a distance. Dr. Macintyre showed how these might be utilised so that students in a classroom of a medical school could hear the chest sounds of a patient in a hospital at a distance. The slight disadvantage of the apparatus at present is that it is extremely sensitive, so that other sounds may sometimes be heard at the same time. The apparatus consisted of a microphone specially adapted for application to the human body, an induction coil to transmit sounds to a distance, and a small battery and telephone receivers, of which the Ader has been found to be the best. By such means it will doubtless be possible to fit up medical schools so that large numbers of students may be trained at the same time to appreciate the sounds heard within the body, even though the patient may be at a considerable distance, and with improvements in the recording apparatus of the phonograph to take permanent records of the same.

The Altona Central Station.—A recent issue of the *Elektrotechnische Zeitschrift* contains a description, by Mr. F. Uppenborn, of the Altona electricity works. The system used at Altona is similar to those of Barmen and Hanover in the use of comparatively large accumulator storage in combination with a three-wire system; but it differs in many interesting details, especially in the use of an earthed middle wire—a principle which found application here for the first time. The first difficulty was that of water, of which the supply was not sufficiently large, and a well was sunk to a depth of 200ft. to obtain the amount required. The construction was begun on July 14, 1891, the first run was on February 1, 1892, and the official opening took place on March 15; the preliminary installation being for 24,000 30 watt lamps, and the space provided sufficing for 80,000 lamps. The machinery consists at present of two boilers, by Berninghaus, of Duisburg, and two vertical triple-expansion engines with jet condensers, by Schichau, of Elbing, fitted with all conveniences, and coupled directly to the dynamos, which are the ordinary Schuckert disc armature machines of 250 kilowatts output, of a height of about 10ft., and having commutators about 6ft. in diameter, with 700 sections. To prevent side pull, the armature is adjustable between the poles; the volts are from 220 to 350, and the amperes 800 to 1,000. Complete details of connections and measuring apparatus are also given in the text, also of the accumulators and cable system. In order to avoid telephone and telegraph disturbances, the middle wire has been laid bare; and this has hitherto been quite successful in preventing disturbance, even when short circuits take place. The cables are laid directly in the ground, as usual in Germany, and protected by U-iron at crossings, etc. The tests resulted as follows: 7·41b. of steam per 1lb. of coal, 86·5 per cent. of the heat in the coal being utilised. The steam-engines used 15·5lb. of steam per indicated horse-power, and the average efficiency of each steam-dynamo was 82 per cent.; and 0·78 electrical horse-power hour was produced per kilogramme of coal burnt. The automatic constant-current system of charging the cells has been employed here with excellent results.

The Pacific Cable Question.—The Postal Conference arranged towards the close of last year between the Governments of the various Australasian colonies was opened at Wellington on Monday, under the presidency of Mr. J. G. Ward, Colonial Treasurer, Postmaster-General, and Minister of Trade and Customs for New Zealand. The colonies of New South Wales, Victoria, South Australia, Queensland, West Australia, and Tasmania were represented, either by Ministers or by the chief officers in charge of the Post Office departments. On Tuesday the proposed Pacific cable was reconsidered. The various schemes which have been formulated for laying a cable to connect Australia with North America was discussed, and the conference declared itself in favour of a line starting at Bundaberg, in Queensland, and proceeding thence to Samoa, Fanning Island, Honolulu, and Vancouver. This was regarded as a most feasible commercial route for a cable under the Pacific, and as being likely to enlist the support of Great Britain, Canada, the United States, Germany, and France. When the conference resumed on Wednesday Mr. Ward moved: "That,

Digitized by Google

considering the important interests involved, both of a national and commercial character, in the establishment of a Pacific cable, the representatives of the respective colonies assembled at this conference recommend their Governments to consider the desirability of entering into an agreement with the other countries interested, for a period not exceeding 14 years, to guarantee the interest at the rate of 4 per cent. per annum on a capital of not more than £1,800,000 to any company undertaking to lay a Pacific cable, on condition that the tariff charged does not exceed 3s. per word for ordinary telegrams, 2s. per word for Government telegrams, and 1s. 6d. per word for Press telegrams to and from Great Britain and the colonies; the United Kingdom being asked to join in the guarantee, and the routes of the cable being either of the following: Brisbane to Ahaipara Bay (New Zealand), Suva, Apia, Fanning Island, Hawaii, and Vancouver, or from New Zealand by the same route to Vancouver." The motion was seconded by Mr. John Kidd, the Postmaster-General of New South Wales, and after a lengthened debate the matter was adjourned.

Messrs. Crompton and Co.'s New Catalogue.—It is now some four years since Messrs. Crompton and Co. issued a complete catalogue of electrical machinery and apparatus, and during the interval very considerable progress has been made in the many different applications of electricity. Mr. Crompton, it will be remembered, visited the Paris Exhibition in 1878, and brought back with him two Gramme dynamo machines, which formed the commencement of the now well-known works at Chelmsford. Since that time the business of the company has been extensively developed, and, in addition to having three large works, the company have important agencies in nearly all parts of the world, as, for instance, in Australia, Germany, Russia, France, Rangoon and Burmah, Japan, and Bengal and North-West Provinces. The three works in question are respectively at Chelmsford, where heavy machinery is constructed; at Lillie-road, London, S.W., for light machinery; and at 158, Brompton-road, S.W., for what the company are endeavouring to largely popularise—namely, electric heating and cooking apparatus for use in hotels, clubs, and restaurants, and for domestic purposes; whilst the chief offices are situated at 4, Queen Victoria-street, E.C. The present has been deemed an opportune moment to bring out a new catalogue, and the copy lying before us may be regarded as one of the most complete in the country. For convenience of reference, the catalogue, which is largely illustrated, has been divided into sections. The first comprises notes, data, and prices relating to dynamos, motors, and steam-dynamos. Here one finds practically all information that a purchaser may desire on Crompton machines, single, or coupled direct to a Willans or Chandler engine, or to a Belliss engine for shiplighting. In the second section, the applications of motors for driving lifts, pumps, and haulage engines for colliery purposes, cranes, electric tramcars, and for other purposes requiring power for industrial processes, etc.—and in which direction the company have taken a very prominent part—are fully set forth. The Crompton-Brunton alternate-current system forms the subject of the third section, and in this connection it is noteworthy that the company are fully competent to deal with alternating-current plant, as, indeed, they have done so in various cases. The next section treats of arc lamps, lamp-posts, brackets, lanterns, projectors, etc., and in this field, too, the company are meeting with success, and particularly in regard to the Crompton-Pochin arc lamp. The remaining sections relate to measuring instruments, notes, data, and estimates of cost of the electrical transmission of power, controlling apparatus, switchboards, and to underground mains on the Crompton and Crompton-Davies systems. A long list of testimonials, referring to central stations and private installations carried out by the company, affords abundant proof of the high-class character and efficiency of the work executed, and forms an appropriate conclusion to this extremely useful catalogue, of which a revised but smaller edition for the pocket will shortly be issued.

Indicating the Position of Ships in Harbour.—Mr. Charles A. Stevenson has been making experiments for locating the position of vessels at harbour entrances, which would be of service when, during certain states of the weather, other observations cannot be easily made. He proposes that a cable might be laid down in the sea, and by changing the electric state of the cable, vessels passing near or over it might be able, by means of a detector on board, to discover that they were in its vicinity. Some experiments showed the method to be feasible, since the sea offers no insurmountable difficulty, and he has constructed two instruments which will act through 180ft. of water. The first instrument is a coil of uninsulated copper-wire rope dipping into the water at the bow of a boat, and a similar water connection at the stern. If these are joined by a wire with a telephone on the circuit, it will be found that even without an induction coil or other arrangement to magnify the effect, a very sensitive instrument is produced, and that, when the wires from bow to stern of the boat are at right angles, or nearly so, to a cable laid in the water at some distance from it, the sounds produced by a magneto-electric machine connected to one pole of the machine are audible in the telephone. If the water connections are equidistant from the cable, as they would be if the boat were immediately over the top of it, or lying broadside on, no sound is heard. The action takes place when the coils in the water are insulated. The cable also may be insulated or uninsulated. The action is similar with an induction coil, and will also act if the potential of the cable is charged and is then kept so. With the coils separated 10ft. (at the bow and stern of a small boat put down from the vessel) and an insulated wire 400ft. in length laid through a small lake of brackish water 15ft. deep, the alterations produced by the bobbins of a magneto-electric machine were perfectly distinct at the end of the lake 340ft. away from the wire, and the limit of audibility could not be ascertained. Further trials will be necessary to determine the law of the falling-off of the intensity of the sound with the increase of the distance from the cable for a given fixed distance between the water connections, as well as to determine the law of increase of intensity for any increase of distance between the bow and stern connections for a given fixed distance from the cable. Mr. Stevenson's second instrument is a coil of insulated wire surrounding a core (that is, an electromagnet with a telephone in the circuit of this coil). With this instrument the making and breaking of the current produced through a wire 200ft. in length could be detected through 60ft. of salt water. When sunk in water the sound seems just as loud. He is of opinion that the action of the instrument consists in the break, if broken sufficiently rapidly, including a current in the coil, which the core intensifies immensely. The sound in a Bell telephone with the instrument was almost deafening with 15ft. depth of water. This electromagnet system of induction, in contradistinction to the parallel-wire systems, has no earth connection, being entirely insulated, and must therefore be a case of true induction through water.

Lighthouse Illuminants.—In the course of an article on this subject, the *Times* says: "It is doubtless within the public memory that the prolonged investigation at the South Foreland about 10 years ago into the relative merits

Digitized by Google

of oil, gas, and electricity as lighthouse illuminants resulted in a declaration by the Trinity House Committee that, for all practical purposes, the lights of oil and gas were about on an equality, oil being somewhat cheaper, and that the electric light was most suitable for salient points and landfalls, for which the longest possible range is desirable for the lights intended to mark such points. Generally speaking, the matter stands now where it was left by the Committee of Investigation. The conclusions then arrived at have not been seriously disputed; indeed, they have been practically accepted by the French, American, and other foreign lighthouse authorities as fairly representing the facts of the case. But progress has been made in developing the possibilities of each illuminant. Electric lights are being made more powerful than ever. With the continued advance of knowledge respecting the generation and utilisation of powerful electric currents and the adaptation of lenticular apparatus to arc lights so produced, most wonderful effects are now being exhibited. It is not long since St. Catherine's Point, in the Isle of Wight, was lighted with the most powerful electric light then known. Some few years later in the lighthouse on the Isle of May, in the Firth of Forth, was installed an electric light whose power greatly exceeds that of the St. Catherine's beam. Now we hear that in France they have electric lights transcending in power and distinctiveness everything on this side of the English Channel. The British Government some time ago agreed that luminous intensity could only be expressed satisfactorily in candle-power, and the engineers of the three general lighthouse authorities for England, Scotland, and Ireland were authorised to determine the candle-powers by actual measurement of all the lights as issuing from the lighthouse lanterns. Measurements were accordingly made in the photometric-room at the South Foreland, where types of every burner, associated with exemplar lenses, were measured under the joint direction of the three engineers—Mr. T. Matthews for the Trinity House, Mr. D. A. Stevenson for the Scottish and Mr. William Douglass for the Irish Lighthouse Board. The results so gained were expressed in candles, and each record was the mean of a great number of photometric observations. The figures were then submitted to a conference, which agreed to accept the figures given as applicable to the oil and gas lights. With the electric lights some difficulty has been experienced. It is well known that considerable doubt exists respecting the extraordinary candle-powers claimed for electric lights, based mainly on the electrical energy developed for producing such lights. There seems, indeed, to be some difficulty in bringing the bluish arc light to an effective comparison with the yellow light of a candle, and the most practised photometrists are not absolutely certain that they can make the comparison accurately. This question is therefore for the moment standing over, in order that actual measurements of the lights may be made with the most approved means. The conference hesitated to publish officially figures based on imperfect data, and this matter is now receiving careful attention with a view to a trustworthy determination being arrived at.

The Electrolysis of Sea-Water.—The experiments now being made at Worthing with the Hermite process are attracting considerable attention, and the opinion of a *Lancet* correspondent on the subject will prove interesting. The correspondent states: "The Hermite system of sanitation is based on the use of what is declared to be a very powerful disinfectant liquid obtained by submitting sea-water, or a solution of common salt and chloride of magnesium to the action of a current of electricity in a machine called the "electrolyser." The magnesium chloride is alone decomposed, the chemical affinity between the positive element magnesium and the negative element chlorine being distinctly weaker than that existing between the elements of common salt; but the undecomposed sodium chloride serves as an electrical conductor. The exact nature of the changes produced in sea-water by this treatment is not perfectly understood, but it is well known that when a current of electricity is passed through a solution of common salt (NaCl), which is divided loosely into two columns of liquid by a diaphragm of parchment, or, if the experiment be performed in a V-tube, with an electrode in each limb, caustic soda appears at the negative pole, and chlorine at the positive. These products, however, if left to diffuse would combine, according to the equation $2NaOH + Cl_2 = NaClO + NaCl + H_2O$, and form sodium hypochlorite. This is probably what takes place in the electrolyser of M. Hermite, except that hypochlorite of magnesium is formed which yields its chlorine more readily than the corresponding sodium salt. The action, however, is not so seemingly simple, since other bodies of a powerfully oxidising nature are invariably associated with the electrolytic products. The Hermite fluid has a slight but not unpleasant chlorous odour, is said to be neutral to test-paper, and rapidly displaces iodine from potassium iodide. It possesses distinct bleaching properties, and this fact introduces some doubt as to whether the process is applicable to inland towns since the discharge of a chlorinated liquor into rivers would most probably prove fatal to fish. The electrically-treated sea-water, the strength of which is regulated by the rate of flow through the electrolyser, is pumped into elevated tanks, from which the water-closets of the cottages in the row in West-street are supplied. The closet evacuations flow first into an intercepting syphon, and this is an essential feature in the system, inasmuch as it is claimed that all accumulated solids are gradually disintegrated and dissolved by the passage of a constant supply of electrolysed sea-water through the syphon. There was an accumulation of paper and soap and other sewage concomitants in this syphon, which represented the product of three weeks' use of the sewer. The quantity of deposit was certainly considerably less than one would expect to find in the case of untreated sewage, while it was quite free from fæcal odour. It is even advanced that such things as paper are gradually broken up by the modified sea-water. In an interview with M. Hermite, which he freely accorded me, I expressed myself somewhat incredulous on various points. His replies are of interest. Thus, on the question of the possible injurious action of the fluid on service pipes and reservoirs, he said that it has a preliminary action on iron, which, however, is soon arrested by the protective crust of oxide first formed. In bleaching factories all the machinery is of iron, and it shows little or no deterioration after several years' use. It would be possible, he added, to use earthenware or cement pipes; but they were absolutely unnecessary, for he was prepared to guarantee that tarred iron pipes would prove satisfactory. The pipes and tanks used in the experiment at West-street were of galvanised iron, and after some time they would be found to be coated with a protective layer of magnesic oxide. On the question of cost M. Hermite said that to supply the inhabitants of Worthing with not merely enough water for the closets, but also for domestic use—to enable them to have, in fact, a disinfectant to use for washing floors, sick-chambers, and so on—would cost about 1s. per head per annum of the population; that would mean about 40 litres (nearly nine gallons) per head per day. But for closets only, leaving a margin for town purposes, it would cost about 6d. per head per year of the population."

Digitized by Google

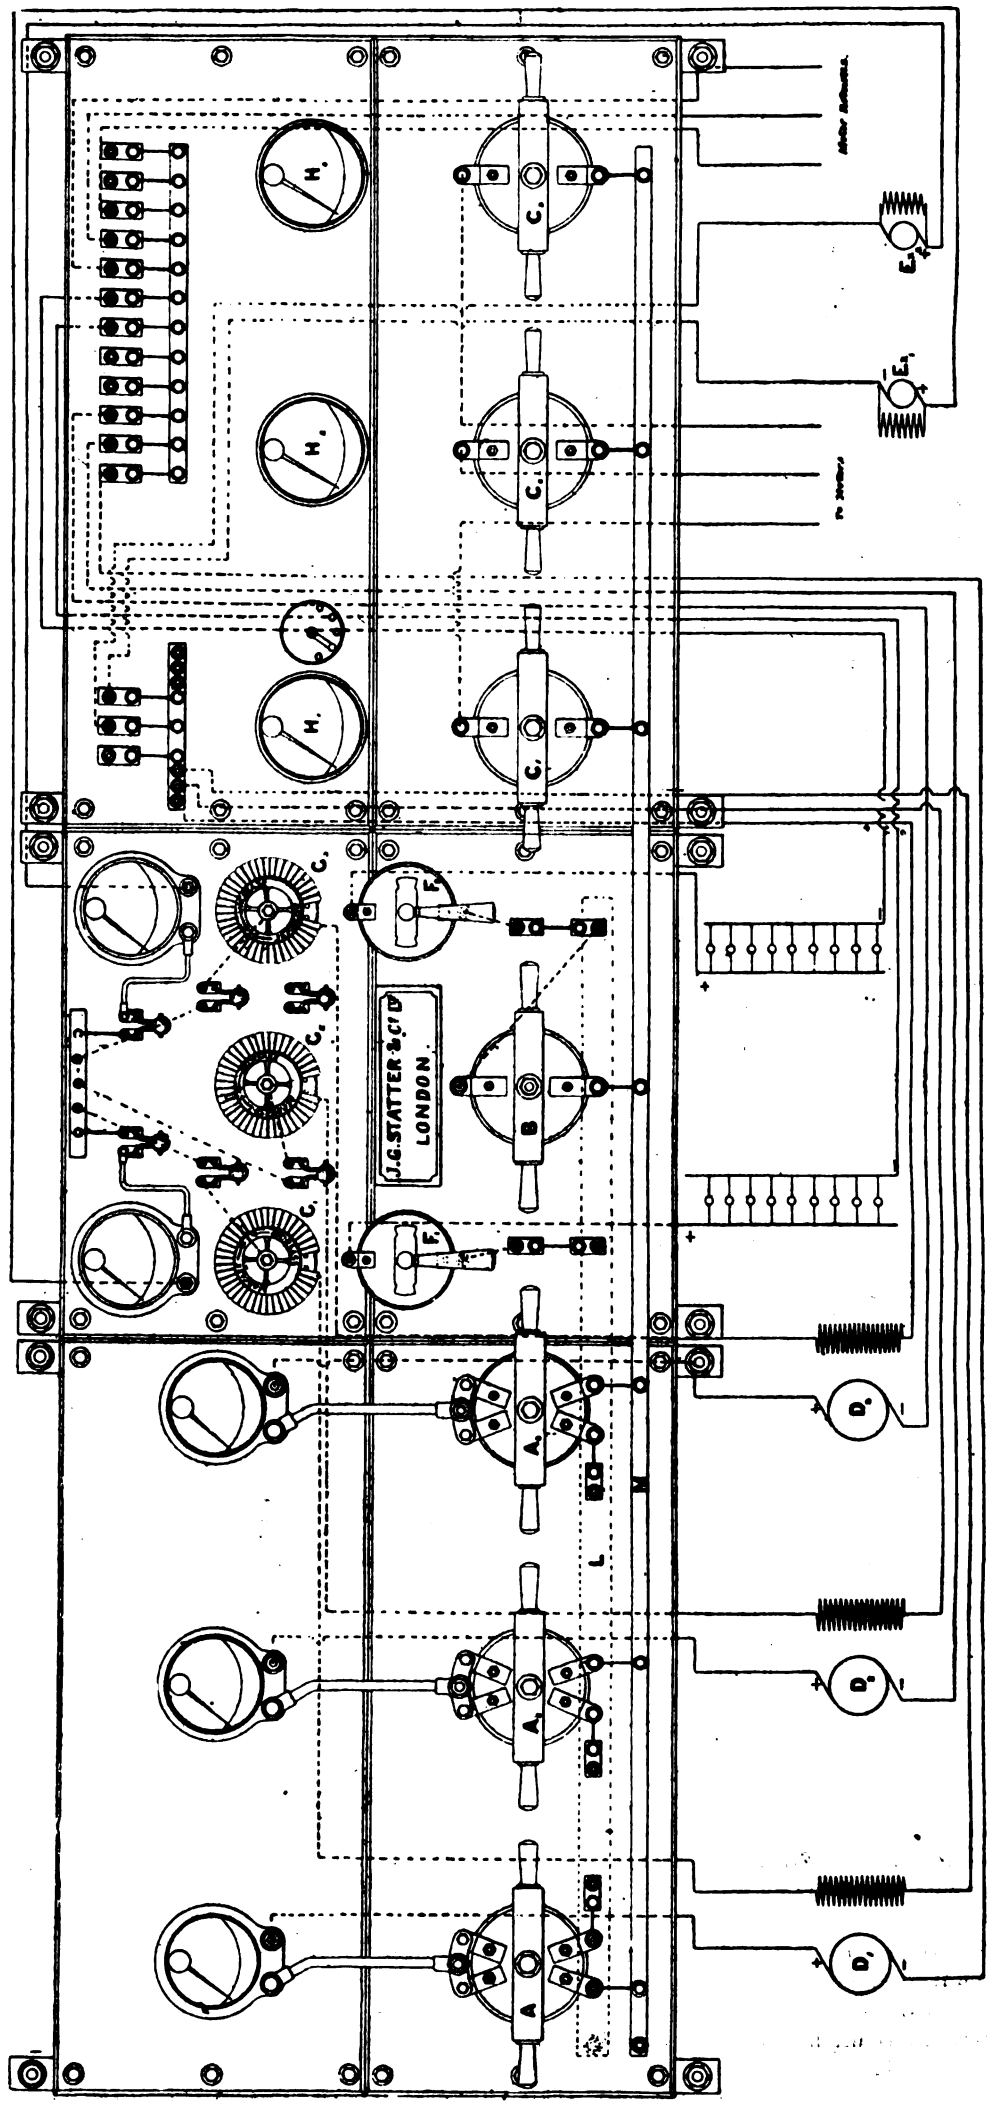
SWITCHBOARD FOR LIGHTING AND MOTOR CIRCUITS.

For some time past there has been in active operation at the works of Messrs. W. T. Henley's Telegraph Works Company, Limited, an electric generating station of considerable size supplying current to lights, both incandescent and arc, as well as to a number of motors throughout the different shops and departments in the works.

When finally completed the plant will be capable of an output equal to nearly 500 h.p., there being eight Crompton dynamo generators then erected of 50 h.p. each, driven by belts from two countershaft extensions coupled to the crankshafts of high-speed vertical compound engines made by Belliss and Co.

Perhaps the most interesting feature of the installation, from an electrical point of view, is the main switchboard erected on one side of the engine and dynamo room, and which we illustrate herewith in diagrammatic form. In the engraving, D_1, D_2, D_3 represent the three large generators at present installed; the current from their positive terminals passes through ammeters placed on the top left-hand side of the board, and thence to a two-way switch, A_1, A_2, A_3, for each machine. These switches serve to join up any of the dynamos to one or other of two positive omnibus bars, L, M, connected respectively to the lighting and the motor circuits; M, as will be seen, is mounted on the front of the board, whilst L is at the back. The connecting links are formed of fuse wire, so that a system of double-pole fuses exists.

Both positive bars may be coupled together for running in parallel by means of the switch, B, similarly provided with fuse links. The system of distribution adopted is that of a simple two-wire parallel at low voltage, the pressure employed being 110 volts. The switches marked C_1, C_2, C_3 control the motor circuits, whilst F_1, F_2 serve as main switches for the lighting circuits. All these switches



Switchboard for Lighting and Motor Circuits, as erected at the works of Messrs. W. T. Henley's Telegraph Works Company, Limited, North Woolwich

Digitized by Google

are of the ring contact type, in order to ensure plenty of surface in actual hard contact. Ex_1, Ex_2, represent the two exciting machines employed to furnish current for the generator fields, and G_1, G_2, G_3, are regulating switches which control by means of step-by-step resistances the exciting current through the field coils, hand regulation being found sufficient to keep the voltage constant, even under the heavy variations of motor work.

Of the six small switches grouped near the latter, three—as may be seen by tracing the connections—serve to cut in or out the generator fields; two others convey the main current from exciter dynamos through ammeters to a small positive bar at the top of board (whence connections are made with the three switches just mentioned); the sixth is a spare.

At H_1 is a voltmeter for testing the pressure of each generator, an adjacent five-point switch allowing each machine to be tried before switching in or out of main circuit: H_2 and H_3 are similar instruments for measuring the voltage of the lighting and motor positive omnibus bars.

The switchboard thus described has been made by Messrs. J. G. Statter and Co., Limited, to the designs of Messrs. Kincaid, Waller, and Manville, who have acted as consulting engineers upon this installation.

ALTERNATING CURRENT AND THE LOW-TENSION DISTRIBUTING NETWORK.*

BY E. PARRY, B.SC.

My object in bringing this subject before you is to show how, in designing a network which is supplied by an alternating current, the extra drop due to inductance, over and above the drop due to dissipation of energy in the copper, can be taken into account with very little extra trouble over that entailed in designing a network for continuous currents. Engineers have been so accustomed to deal with quantities involving, for the purposes of calculation, their magnitudes alone, that the vector properties of the quantities involved in alternating work are apt to be overlooked, or, if recognised, shunned, though there is no further difficulty than that of applying the laws governing the manipulation of complex quantities given in every textbook on algebra. Oliver Heaviside has evolved a complete vector system for the treatment of physical quantities in general with particular application to electromagnetism, but in ordinary engineering practice we are mainly concerned with maximum values or the square root of the mean square of the values of harmonically varying quantities, for which the simple laws of vector algebra suffices, with the application of which we are now becoming familiar through the efforts of Heaviside, and, more recently, to Steinmetz and Kennelly. Given the complex expression $(R+ipL)$ for the impedance of a coil, and $(K+ipC)$ for what Heaviside calls the admittance of a condenser, or leyden (where R = resistance of a circuit, L = induction, K = conductance of dielectric of the leyden, C = capacity of leyden, $p=2\pi n$, where n = number of alternations per second, $i=\sqrt{-1}$), then the sum of a series of impedances and admittances or the resultant of a multiple circuit of impedances and admittances are as easily expressed as the corresponding simple quantities.

For instance, the sum of any number of impedances, R_1+ipL_1; R_2+ipL_2; R_3+ipL_3, etc., is

$$\{(R_1+R_2+R_3+\ .\ .\ .\ )+ip\,(L_1+L_2+L_3+\ .\ .\ .\ )\},$$

and the sum of the several potentials, $C\,(R_1+ipL)$; $C\,(R_2+ipL_2)$, etc., as measured by a voltmeter will be

$$C\,\{(R_1+R_2+R_3+\ .\ .\ .\ )+ip\,(L_1+L_2+L_3+\ .\ .\ .\ )\}$$

volts, as measured by a voltmeter, the terminals of which includes the whole in series if C = current in amperes as measured by an ammeter. Equally simple is the process of finding the resultant of any number of impedances and admittances in parallel on the principle that the reciprocal of the impedance of the compound circuit equals the sum of the reciprocals of the individual components, provided that there is no mutual action between the circuits, and we have as a result an expression of the form $(A+iB)$: for the product and dividend of complex quantities yields another complex quantity.

For such cases this method is much simpler than the ordinary Cartesian projection method, and has the merit of not obscuring the vectorial significance of quantities concerned, which indeed may be said to be the *raison d'être* of Heaviside's methods. I need not do more than just indicate the processes before this society, and I proceed at once to the main object of this paper, which is to describe the application of these principles to network design.

To illustrate the principle it will be quite sufficient to consider a network on the two-wire system. Given the detailed demand for any area, it is comparatively simple to plan the network for that area for a continuous current with the limit of drop allowed by the Board of Trade at maximum load. I mean, of course, only as far as the arithmetical process is concerned, and apart from the advantage of an almost unerring judgment that enables men of experience in such work to design off-hand the most economical distribution of copper. Arithmetically, all that is necessary is to see that the sum of the individual $C \times R$ "drop" between the feeding points and neutral points does not exceed at full load that which would bring the potential below the Board of Trade limit. But for alternating work, a most grievous mistake would be made if inductance were neglected—that is, if the several "drops" are not summed vectorially—unless it is recognised that the drop is not $C \times R$, but $C \times (R + ipL)$. The consequence will be that the volts obtainable at the farthest or neutral points will be much less than the Board of Trade limit—as much as 4 or 5 per cent. below, for a distance of 6in. between centres in an area of one-tenth of a square mile, for circuits of unit inductivity of medium and material—even if the feeding points be at the potentials estimated for. Another consequence will be that at each junction the current will divide inversely as the impedances and not as the resistances, and so upset the intended distribution of current through the feeders, and perhaps through the load on a feeder, the least to be desired, but having regard to the vagueness and uncertainty in the best possible estimate of demand this last is relatively unimportant. Usually the influence of self-induction upon the effective "drop" in a network has been neglected upon the plea that the self-induction is small; the values met well do certainly seem insignificant. From 10,000cm. to 20,000cm. are the values usually met with in this class of work, but the true criterion is the time constant, $\frac{L}{R}$, of the circuits; thus in a part of a network, say, 100 yards long and 6in. between centres, and for a 0·15 square inch conductor of 1·0 square inch section, the effect of self-induction upon the drop may be negligible, but for a feeder having the same value of L, the ratio $\frac{L}{R}$ is such that the inductance of the circuit cannot be neglected. In other words, the relative values of L and R determines the direction of the vector, which is of equal significance with its magnitude—*i.e.*, it determines the lag, which differs enormously in the two cases. The same reasoning applies to armatures. Armatures with no iron in them are said to have negligible inductance, and such figures as ·002 secohm or 2×10^6cm. are quoted. Nevertheless, when the quantity pL (where $p=2\pi n$) is compared with the resistance, R, of the armature, self-induction is everything, and is far and away the chief factor in the expression for impedance.

To mark a network according to the above principles seems formidable, but by approximations, or by tables, it has proved to be remarkably simple. We have tables of resistances given us, and obviously the first thing to do is to find the value of the L—the self-induction of the particular length of circuit under consideration. The expression for the inductance per unit length of two parallel wires is given by Clerk Maxwell in its most general form, which, when reduced, becomes

$$\frac{L}{l}=\left\{2\,\mu_0 \log_e \frac{b^2}{a_1 a_1'}+\tfrac{1}{2}\mu\right\} \text{ centimetres,}$$

where l = length of circuit in centimetres—*i.e.*, half the

* Contributed to the Physical Society of Glasgow University.

Digitized by Google

length of wire—b = distance apart of wires between centres, a_1 and a_1' are the radii of the two wires, μ_0 the inductivity or permeability of the medium, μ the permeability of the material of conductor. For air, $\mu_0 = 1$, and for copper $\mu = 1$; and if the two radii, a_1 and a_1', be equal, the equation reduces to

$$\frac{L}{l} = 4 \log_e \frac{d}{a} + 0{\cdot}5.$$

If the distance of conductors between centres be approximately constant, it is advisable to calculate beforehand the self-induction per unit length of circuit for all the different sizes of wires to be used, or, better still, calculate $\frac{L}{l}$ for two or three sizes of conductors, plot and draw a curve from which to obtain all intermediate values.

I have plotted such a curve in Fig. I. for a distance between centres of 6in.; the abscissæ correspond to the cross-sectional area of the parallel wires, and the ordinates are the self-induction of unit length of circuit in centimetres.

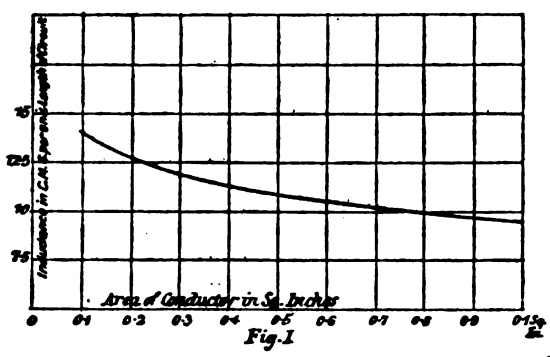


Fig. I

In general, what we require is the "drop" at the end of a line of which the length, resistance, self-induction, and potential at source is known, shown diagrammatically in Fig. II. A is the source at which the potential V_0 is known, l the length of each line of resistance and inductance, R/2 and L/2. The load consists of an impedance $(R_1 + ipL_1)$ in parallel with an admittance $(K + ipC)$. The resultant impedance at the end of the line

$$= \frac{1}{(K + ipC) + \dfrac{1}{R_1 + ipL_1}}$$

which can be reduced to the form

$$\frac{R_1 + ipL_1}{A + iB + 1}; \qquad \text{where } A = (KR_1 - p^2 CL_1)$$
$$B = (pKL_1 + pCR_1).$$

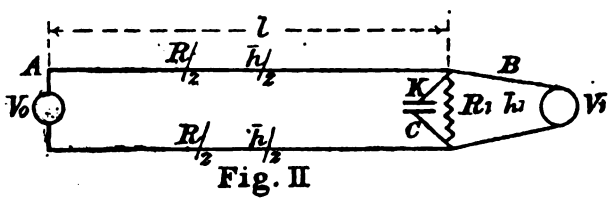

Fig. II

If I be the main current passing through as measured by an ammeter, the potential V_1 as measured by a voltmeter will be

$$V_1 = I\left\{\frac{(R_1 + ipL_1)}{A + iB}\right\},$$

and

$$V_0 = I\left\{(R + ipL) + \frac{R_1 + ipL_1}{A + iB}\right\},$$

which reduces to the form

$$V_0 = I\left\{\frac{A' + iB'}{A + iB}\right\}.$$

Practically, this problem is immensely simplified, as the load, being a lamp load, is non-inductive, and the capacity effect is negligible, the impedance of the load is reduced to R_1 simply, and $V_1 = IR_1$,

and

$$V_0 = I\{(R + ipL) + R_1\};$$
$$= I\{(R + R_1) + ipL\}.$$

The "drop"

$$V_0 - V_1 = I[(R + R_1) + ipL] - IR_1.$$

This is then the condition obtainable in a distributing network. In the expression $I[(R + R_1) + ipL]$, R_1 is the only unknown quantity, which can be easily obtained from the polar equivalent $x(\cos\theta + i\sin\theta)$, the modulus x we know to be $\frac{V_0}{I}$, and we have

$$[(R + R_1) + ipL] = \frac{V_0}{I}(\cos\theta + i\sin\theta).$$

Thus, if $V_0 = 100$ volts and $I = 200$ amperes by the measuring instruments—

$$\frac{V_0}{I} = \tfrac{1}{2}; \quad \tfrac{1}{2}\sin\theta = pL; \quad \sin\theta = 2pL,$$

from which θ is obtained, and therefore $\cos\theta$; then

$$\tfrac{1}{2}\cos\theta = R + R_1,$$

which gives us R_1, and finally $V_1 = IR_1$.

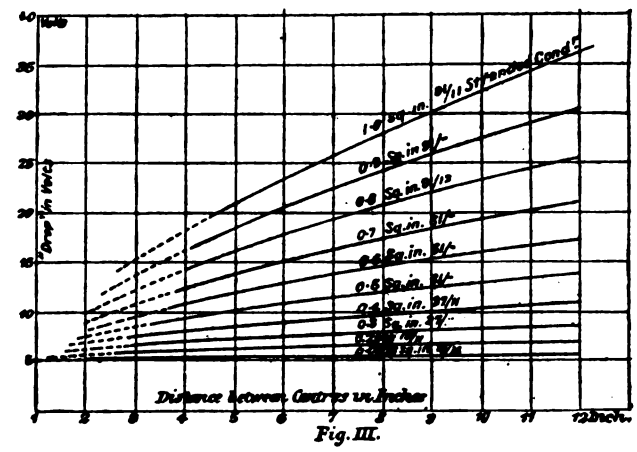

Fig. III.

This can be done at each successive step in the network design, but obviously the more practical way is to obtain an empirical expression, or, given a nearly constant distance between centres, to plot a series of curves from which the resultant "drop" of impedance and resistance can be read off at a glance. Curves, Fig. III., are plotted in accordance with the foregoing principles, and show how the drop varies with different distances between centres. The abscissæ represent distances from centre to centre in inches. The ordinates show the drop in volts under the following conditions. The length of the circuit is 100 yards. The potential at the source is 100 volts. The current in each case is that which gives 1,000 amperes per square inch, and is a mere convention. The lines start from a distance between centres at which the conductors would touch, and are drawn dotted up to a point at which their insulations would touch if covered. The inductance for this length is calculated from

$$L = 100 \times 91{\cdot}44\left(4\log_e\frac{d}{a} + 0{\cdot}5\right) \text{ centimetres.}$$

$$= 100 \times 91{\cdot}44\left(4\log_e\frac{d}{a} + 0{\cdot}5\right) \times 10^9 \text{ secohms.}$$

The resistance is that given in the manufacturer's tables for the corresponding sizes of stranded conductors, but corrected for non-equal distribution of current. Using Lord Rayleigh's formula,

$$R = R_0\left(1 + \tfrac{1}{2}\frac{p^2 l^2 \mu^2}{R_0^2} - \frac{1}{180}\frac{p^4 l^4 \mu^2}{R^4} + \text{etc.}\right);$$

where R_0 is the ordinary resistance for symmetrical distribution of current, l = length of conductor, μ = specific resistance of conductor, $p = 2\pi n$. If $n = 100$ ⌒⌣ per second, and a = radius of conductor, the equation reduces to $R = R_0(1 + \cdot 12\,a^4)$ for a copper conductor. Throughout the paper, the potential at source = 100 volts, which I specify, as the "drop" will vary with the potential for the same length and properties of circuit; also, $p = 2\pi n$, where $n = 100$ ⌒⌣ per second.

Suppose the distance between two parallel conductors of 0·5 cross-sectional area is 6in., we obtain, from Fig. III., for this a "drop" of 10·75 volts at the end of a circuit, each line of which is 100 yards, the potential at the source 100 volts, the load non-inductive, a current

Digitized by Google

of 500 amperes passing through, and $n = 100 \sim$ per second. Now having fixed upon a distance between centres, the "drop" will of course vary with the length of the circuit and with the current passing through. Fig. IV. shows the "drop" for varying length and constant current.

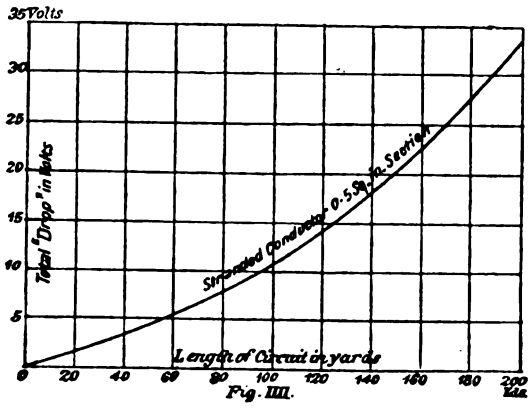

Fig. III.

The abscissæ show length of circuit in yards, and the ordinates the corresponding "drop" in volts, the conductor is a 0·5 stranded cable, current 500 amperes, potential at source = 100 volts, and alternations = 100 per second. Fig. V. shows how the "drop" varies with the current for the same length of circuit; the conductor is again 0·5 square inch section, the length of circuit = 100 yards. The abscissæ show current in amperes, and the ordinates the "drop" in volts.

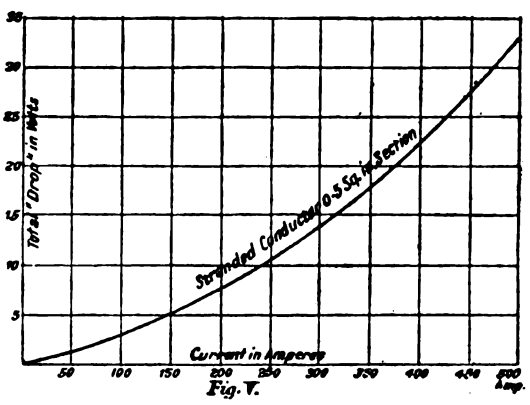

Fig. V.

150 yards, 100 yards, and 50 yards are a series of curves showing the drop for different current densities from 1,000 per square inch down to zero, and marked 0·9, 0·8, 0·7, etc., 1,000 per square inch being unity. Thus, suppose the circuit is 150 yards long, and formed of copper 0·5 square inch section with 6in. between centres, and suppose 200 amperes carried through; on the 0·5 curve at 150 yards for a current density of 1,000 per square inch we read 20·15. Following this curve for varying currents from the point until we come to ·4, which corresponds to 200 amperes on the 0·5 square inch cable, we read 5·19 volts, which is the "drop" obtainable. The resistance "drop" is $\frac{\cdot 05 \times 300 \times 200}{1{,}000} = 3{\cdot}0$ volts, where ·05 = resistance per 1,000 yards as given

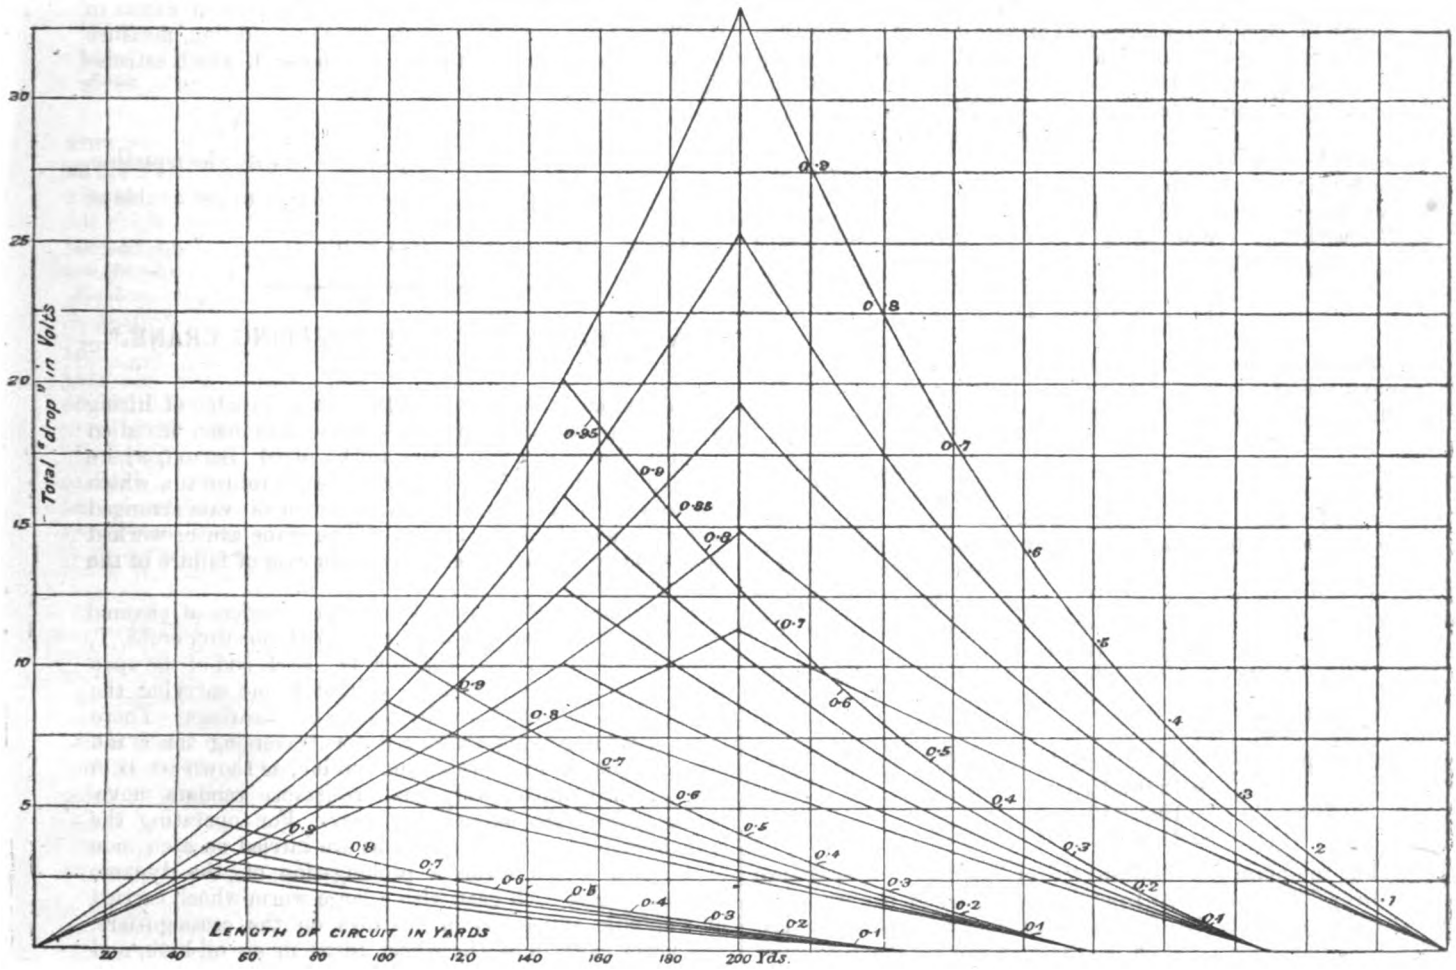

FIG. VI.

The next step to take in order to obtain convenience and despatch in marking a network is to combine the curves of Fig. IV. and Fig. V. for the sizes most generally used. I have plotted such a series in Fig. VI. for the sizes indicated. I have assumed a constant distance between centres of 6·in. and a potential of 100 volts at the source. Starting from the left-hand corner are curves for the sizes indicated showing the "drop" for all lengths of circuit up to 200 yards, and for a current density of 1,000 per square inch. Starting from the values of the ordinates at 200 yards, in the manufacturers' tables for a stranded conductor 0·5 square inch section. To this add 14 per cent. due to an increase of resistance for unequal distribution of current for this size, and 100 alternations from Lord Rayleigh's reduced equation, $R = R_0 (1 + \cdot 12\, a^4)$, which brings the resistance "drop" to 3·4 volts.* The difference between this and

* I am much indebted to Mr. Nisbett, of the City of London Electric Lighting Company, for the use of a table of virtual resistances for 100 $\sim$ per second for all sizes of conductors in general use, compiled by him from a formula given by Lord

Digitized by Google

5·19 is the increase due to self-induction—*i.e.*, about 50 per cent.

Strictly speaking, it is not correct to apply the values obtained from these curves to a network, as they are particular values for 100 volts at the source end of the line, but they are quite accurate enough for the range of two or three volts on each side of 100 volts, which is a condition obtainable in networks, and a good deal more approximate than the estimated demand. I have only drawn the curves for varying current for four lengths—*i.e.*, 50 yards, 100 yards, 150 yards, and 200 yards—in order not to complicate the diagram, my object being to show the principle; in practice it is advisable to draw the current variation curves every 20 yards; all intermediate values can be got at a glance by interpolation. The above method works very well for one fixed set of conditions, and I can thoroughly recommend it; it is worth the few hours' labour and saves time.

Everybody dealing with alternating current should possess a table or a curve of self-induction per centimetre such as Fig. I., or, better, a set of curves of $\frac{L}{l}$ with varying distances between centres for the different sizes of conductors; such a table is quite general. Then if he has to deal with network, he should construct a set of curves such as Fig. III., which is limited to a particular condition of his practice, such as the periodicity and the potential at the source, either 400, 200, or 100 volts, as the case may be. As a matter of convenience, in order to be independent of tables of sines and cosines if not convenient, it struck me to try and obtain an empirical expression which would give the desired figure for any length of circuit and any current density. An expression of the form $a + bx$ was found to be very approximate for all distances within the limits laid down in this paper, and probably approximate enough up to 500 yards of circuit—*i.e.*, two lines 500 yards each—in which the drop due to self-induction is separated from that due to resistance, such that a is the ohmic drop, to which, in order to get the real drop for an incandescent lamp load and 100 alternations, but with any potential, it was only necessary to add a quantity bx, the expression is:

$$D\left(\frac{l}{100}\right) + (D' - D)\left(\frac{l}{100}\right)^2,$$

where D is the resistance drop for 100 yards of length of circuit and current density of 1,000 per square inch, l is the length of the circuit, D′ is the actual resultant drop for 100 yards of circuit as obtained on the curves of Fig. III. For example, let the cable be 0·6 square inch stranded, the resistance per 100 yards from manufacturer's list = ·004 ohm, the virtual resistance after correcting for skin effect = ·005 ohm; for 1,000 per square inch current density the "drop" = ·005 × 2 × 600 = 6·0 volts = D; for 100 ⌒⌣ per second 100 volts at the source end of the line for 4in. between centres, and for 100 yards length of circuit. Fig. III. gives 10·75 volts = D′.

Suppose the resultant drop is required for 200 yards, we have $\frac{l}{100} = \frac{200}{100} = 2$,

and drop $= (6{\cdot}0 \times 2) + (10{\cdot}75 - 6{\cdot}0) \times 4,$
$= 12{\cdot}0 + 4{\cdot}75 \times 4,$
$= 12{\cdot}0 + 19,$
$= 31$ volts.

Thus to obtain the resultant "drop," add to the resistance "drop" 12·0, obtained from data supplied by the manufacturers, a quantity, 19, obtained from such a table as Fig. III. depending upon potential and periodicity of the particular circuit. In this case the resultant drop is two and a half times the resistance drop. For any current other than 600 amperes a similar formula applies, and can be combined with the above by introducing another factor depending on the current density. The combined formula is $D\frac{l}{100} \times r + (D' - D)\left(\frac{l}{100}\right)^2 \times r^2$, where r = ratio of actual current to that which gives 1,000 per square inch. Thus, suppose for the same cable the "drop" for 300 amperes is required, this is half of the 600 for which the curve for 0·6 square inch conductor in Fig. III. is drawn out. If the other data are the same, we have for the "drop" on ·6 square inch cable 200 yards length of circuit, 6in. between centres, non-inductive load, and 100 volts potential at source—

$$D = 6{\cdot}0\ ;\ D' = 10{\cdot}75\ ;\ D - D' = 4{\cdot}75$$

"Drop" $= 6 \times 2 \times \frac{1}{2} + 4{\cdot}75 \times 4 \times \frac{1}{4},$
$= 6 + 4{\cdot}75,$
$= 10{\cdot}75$ volts.

If the current is 200, $r = \frac{200}{600} = \frac{1}{3}$,

"drop" $= (6 \times 2 \times \frac{1}{3}) + (4{\cdot}75 \times 4 \times \frac{1}{9},)$
$= 4 + 2{\cdot}1,$
$= 6{\cdot}1$ volts.

Perhaps a better way would be to obtain a table, or a curves like those of Fig. III., for a one yard circuit and 100 amperes, instead of a 100 yards circuit and 1,000 per square inch current density. In any case the above illustrates the principle, as the formula would be similar.

All the values obtained are only on condition that the permeability or inductivity of the medium is unity, and do not apply if the cables are laid apart in an iron culvert or in an iron-sheathed casing of any form. Much less does it apply to a case of the two cables being laid in two iron pipes; indeed, this last condition is absolutely prohibitive for electric lighting by alternating current (for iron pipes concentric cables must be used) where for a 0·5 square inch cable and 100 yards circuit, the extra drop would not probably be more than $\frac{1}{8}$ per cent. Any form of sheathed casing is bad; but to obtain the value of L, a plan which works very well is to lay a pair of cables in the culvert or casing under the actual condition, measure the potential at both ends, find a value of L which satisfies the equation

$$I\{(R \times R_1) + i\,p\,L\} - I\,R_1 = V_0 - V_1,$$

and find such a value of μ_0 as will satisfy the equation $L = l\,(\cdot 4\,\mu_0 \log \frac{d}{a} + 0{\cdot}5)$, and use this value to get a table of L/l for the different conductors in use.

Kelvin in his presidential address to the Institution of Electrical Engineers, and known as the ber, bei formula.

OVERHEAD ELECTRIC TRAVELLING CRANE.*

An overhead electric travelling crane, capable of lifting weights up to a maximum of 10cwt., has been installed by MM. Julien et Cie. in the works of M. Bertou, where it is employed in handling heavy cages of refuse tin, which are treated by being dipped in a number of vats arranged along the length of the factory. The crane can be worked mechanically as well as electrically in case of failure of the current.

The framework consists of two cross girders of channel iron section, carrying a couple of geared hoisting crabs, T, between which is placed a motor, D. Each end of the span rests upon and is bolted to a light frame carrying the traverse wheels, which are fitted with ball bearings. There is no power gearing employed for traversing the crane except a simple hand rope and pulley, as shown at B in Fig. 1; the comparatively small resistance renders movements to and fro exceedingly easy. For operating the crab hoisting barrels, steel worms are carried on each side of a shaft, which forms a prolongation of the dynamo spindle. These each gear with a large worm-wheel, carried by a spindle supported in bearings on the cross girders. The lower portion of the wheel turns in an oil-bath, and upon its extended axle is a collar, over which the lifting chain passes. At one end of the long dynamo, or main driving, shaft is a grooved wheel, A, round which may be passed a rope for lifting by hand should the current fail at any time.

The motor is of the Rechniewski type, constructed by the Société de l'Eclairage Electrique. When under normal load, it requires 15 amperes at a speed of 1,800 revolutions per minute, the pressure employed being 110 volts. The main leads from the source of supply to the motor are con-

* Abstracted from the *Revue Industrielle*.

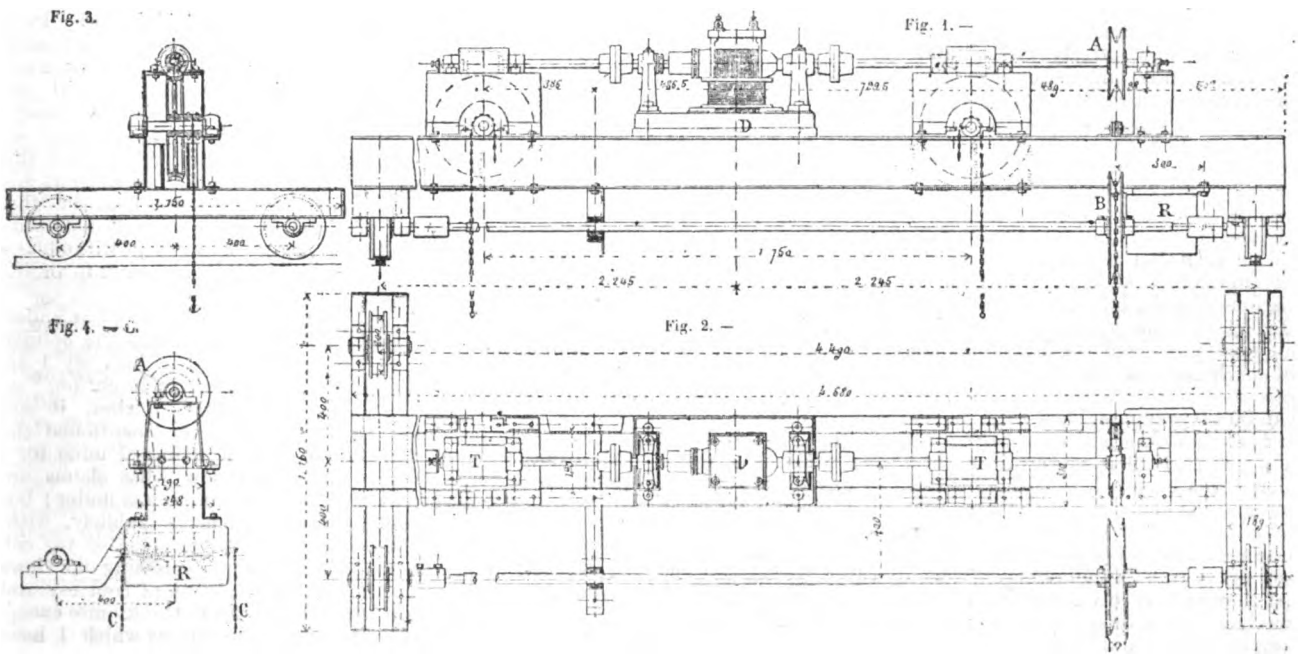
nected to resistances, R, beneath the crane frame, and, in addition, two switches are provided for changing the direction of the current as it is desired to lift or lower away. Starting and stopping are effectuated by means of graduated resistances, which are brought into play by the cords, C (Fig. 4). The ends of these cords are carried to the switch handles, and with a pull one way or the other motion can be given or arrested.



Overhead Electric Travelling Crane.

INSTITUTION OF ELECTRICAL ENGINEERS, Mar. 8.

Mr. ALEX. SIEMENS, President, in the chair.

At last night's meeting of the Institution the following candidates were balloted for:

Members.—Sidney Howard Farrar, Johannesburg, and 69, Cornhill, London; William Claude Hill, European Works, Pownall-road, Dalston.

Associates—Arthur Hinton Allen, Central Institution, Exhibition-road, S.W.; John Edward Dane, 20, Alexandra-road, Selhurst, S.E.; F. R. Davenport, 1, Granville-road, Eastbourne; James Livsey Dyson, 18, Earlham-grove, Forest Gate; John Charles Dwyer, care of Messrs. Grindlay and Co., 55, Parliament-street, S.W.; John R. Gall, the National Telephone Company, Oxford-court, Cannon-street, E.C.; Cecil W. Gwyther, Godstall-chambers, Chester; Owen M. Jonas, 38, Grainger-street West, Newcastle-on-Tyne; Enrique W. Martin, Valparaiso, Chili, and 191, Richmond-road, Hackney; Joseph Horsnell May, 3, Vincent-terrace, N.; Alexander Moir, Engineer's Department, Postal Telegraphs, Leeds; Edward B. Pym, Bar-chambers, Scarborough; J. Clifton Robinson, Managing Director, Imperial Tramways Company, Clare-street House, Bristol; Sherley Sherley-Price, 49, Queen Victoria-street, E.C.; Dudley Stuart, The National Telephone Company, Oxford-court, Cannon-street, E.C.

Students.—Frederick W. Dalton, Seagrove Rectory, Loughborough; Edmund J. Fox, University College, Nottingham; William James Grey, 7, Hill-street, Rutland Gate, S.W.; Percy George Rathbone, Faraday House, Charing Cross-road, W.C.; Ernest Sherley-Price, 49, Queen Victoria-street, E.C.; R. E. Skipwith, Long-row, Nottingham; William Frederick Stuart-Menteth, 48, Chaucer-road, Bedford; Charles F. Wilkin, 8, Wolseley-gardens, Chiswick.

The following paper was then read:

ON PARALLEL WORKING, WITH SPECIAL REFERENCE TO LONG LINES.

BY W. M. MORDEY, MEMBER.

In his reply at the end of the discussion on his Niagara paper, Prof. Forbes alluded to some experiments which he had witnessed, and which he considered showed that alternators of my design would not run properly in parallel. The passage is as follows: "At the time when I recommended the Mordey machine I said that, before deciding to adopt it, tests must be made with a resistance between the dynamos in parallel. Does Mr. Mordey forget that, when he kindly placed at my disposal the means of making this test, by putting 'sunbeam' lamps in series—that is to say, between the two dynamos working in parallel—the lamps went up and down in brightness with the periodicity of a few seconds, and that the tendency was to rise to maximum brilliancy, showing that the dynamos were rather working in series than in parallel? From the moment of those experiments, I felt that that type of machine was not suited for our purposes, though I never mentioned that until I was compelled to by Mr. Mordey's claims for his special mode of working." I heard his remarks with the utmost astonishment, as the experiments, rightly interpreted, appeared to afford the very strongest proof of the exceedingly powerful synchronising effort exerted by these machines, and because I then heard a contrary view expressed for the first time. And in another passage Prof. Forbes stated that they must have alternators at Niagara that will run without any synchronising or waste current.

The matter is of some moment, and demands an explanation. With your permission, I will make this explanation the text and starting point of a paper on parallel working, and on the allied subject of the use of alternators as synchronous motors. The experiments were made in July, 1891, and were mentioned in the *Electrical Review* and elsewhere, in each case as having afforded an illustration of the thoroughly satisfactory parallel working of alternators when directly coupled to high-speed engines—a matter with regard to which there was at that time some uncertainty. It had been supposed that some flexible or yielding coupling was necessary between the engine and alternator. For my own part, I never had any doubt on the subject; but in order to place the matter beyond dispute, some tests were carried out by the Brush Electrical Engineering Company and Messrs. Willans and Robinson. The former provided two of my alternators, the latter fitted them to two Willans engines. Amongst others, Prof. Forbes received an invitation to witness the trial, and was present.

When all the tests of ordinary parallel working had been satisfactorily carried out—including shutting the steam off the engine driving one of the alternators, and then applying a brake to its flywheel in a vain attempt to force it out of step—a further test was made (as an interesting experiment bearing on the subject of synchronous motors) to ascertain what would occur if the two alternators were coupled together with a resistance between them so great that the resistance alone would be sufficient to absorb the whole power of one machine, even if the machine at the other end were at rest; and the remarkable fact was established that even under these conditions (which would be absolutely absurd or impossible in practice) the two machines did not break out of step. The resistance used consisted of "sunbeam" lamps, which happened to be the only suitable resistance available. These lamps, being made for 80 volts and about five amperes, would have a resistance, hot, of about 20 ohms each, and a much higher resistance when cold—probably more than 30 ohms. Seven of these lamps were placed in series between the alternators. There was no other external circuit. It was then found that there was a current passing through them which rose and fell with a slow pulsation; the alternators, although not actually breaking out of step, evidently getting a good deal out of true co-phasal synchronism, and only being pulled in when this slowly pulsating current rose to a considerable amount. Synchronism being regained, the current decreased again. This current was not measured, but was probably about seven amperes, as the lamps were a good deal over-incandesced. The experiment was then discontinued. Properly interpreted, this test appeared to show that even when a line of an enor-

Digitized by Google

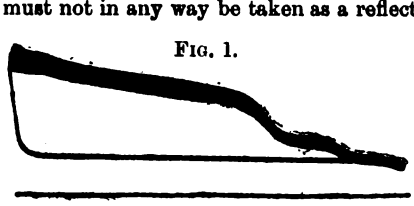
mously high resistance was interposed between two alternators arranged to run in parallel (or one as generator, the other as synchronous motor), and when no adjustments were made to help them to keep together, the tendency to get out of step was corrected with a surprising amount of success. The correction, instead of being instantaneous and powerful, as with machines connected through a small resistance only, being sluggish, and greatly weakened by the effect of the very high resistance of the line.

To show how utterly unfair and unjust Prof. Forbes's interpretation is, and to reassure those who may desire to use synchronous motors, it is only necessary briefly to examine the conditions of the test. The two alternators used in the experiment were 37·5-kilowatt 2,000-volt machines. At full load each would therefore give nearly 20 amperes. Now, suppose it is desired to run one machine as a generator, driving the other as a synchronous motor (to take the illustration that may best suit the case of power transmission over a considerable distance), it will be seen that if the line is to be designed to give such a percentage loss as is proposed for the Niagara-Buffalo transmission—that is, 3·5 per cent.—the loss at full load should be 70 volts, and the maximum current being, say, 20 amperes, the line resistance should be 3·5 ohms. In the actual experiment, the machines did not break out of step even when the line resistance was more than 100 ohms—that is, relatively more than 30 times greater than Prof. Forbes proposes to use even for his long-distance transmission. This is the more striking as a proof of their powerful synchronising when it is considered that even if it had been intended to expend the whole power of the generator in the line, that line should only have had a resistance of 100 ohms. That these machines did not act quite perfectly in parallel under these conditions, even with no load, is not to be wondered at. The only cause for surprise is that they exerted any sensible synchronising effort at all. It is exactly as if an attempt had been made to run two 1,200-kilowatt alternators in parallel through a line constructed to allow a reasonable loss for a couple of 40-kilowatt machines. Even unloaded such a test would be unreasonable.

I now wish to refer to the "hunting" or regular pulsation of current, shown by the slow changing of the lamps from blackness to high incandescence, which is a matter of considerable interest. It may have been caused by self-induction, or, as, in this connection, it is sometimes termed, armature reaction—that is, the effect of the self-induced field produced by the armature in disturbing the impressed field of the field magnet. Although this effect may in some cases be considerable, I think we must look elsewhere for it in this case, because in the machines in question such reaction would have been inconsiderable, even if the phase relation had been most favourable to it. This I may illustrate by saying that if the armature current had been commuted, and passed round coils on the field poles having turns equal in number to the armature coils, the effect on the field would have been inconsiderable. I think an explanation of the "hunting" will be found in the character of the resistance and in the governors of the engines. The change in the resistance of the lamps accounts largely for the pulsation. When black they would interpose a very high resistance—probably about 200 ohms—then, as the machines got a little out of step, the synchronising current would heat them, reduce their resistance, allow a much readier transfer of power, and so bring about a restoration of true synchronism and a reduction of current through the lamps. This series of effects, being constantly repeated, goes a good way towards explaining the pulsation. Probably without this lowering of the resistance by the incandescing of the lamps, synchronism would not have been maintained at all.

Then, again, the governors of the engines must be considered. If they pulsated with the same period, but opposite phase, the action is explained; they would, at any rate, accentuate the "hunting," if they did not start it. Messrs. Willans and Robinson have kindly sent me an indicator card, taken by Mr. Willans at the time, which supports this view, the steam being shown as having been widely varied during the taking of the card. This must not in any way be taken as a reflection on the

Fig. 1.



governors. The conditions were very trying for any governors, there being no load, and no opportunity occurred of specially adjusting them. If we had governed by hand at the stop valve, this "hunting" would not have occurred. Nor would it have occurred if we had adjusted the E.M.F. of one machine so as to allow it to run as a motor all the time. What happened appeared to be a repeated change in the functions of the two machines, from generator to motor—first one racing, and then the other, driving the second one as a motor.

The condition of entire absence of synchronising current or of correction can only be obtained by driving by engines that are very even in power always. I think this is more likely to be approached by turbines than by reciprocating engines. By "synchronising current" I do not mean necessarily an actual current passing from one alternator to the other—this only occurs when one of them is driven as a motor—I mean the variations of the current contributed by each machine to the circuit. But I would like to point out that the condition laid down by Prof. Forbes as an essential—namely, that they must have alternators at Niagara that will run without any synchronising or waste current—is an absolute impossibility. Alternators will run without synchronising current only when there is no necessity for them to exert any synchronising effort. However, I am glad to find that Prof. Forbes has set himself to solve this problem of getting an alternator motor to run without any current (for that is what it amounts to), because I am sure that in solving it he will also have disposed for ever of that other interesting problem—making a motor that will run without any back E.M.F. This is a new and significant outcrop of the "perpetual motion" idea.

I am sure that if Prof. Forbes had really considered or understood this matter he would not have expressed the opinion which I have quoted. At the same time, I wish to say I am convinced that his criticism was not unfair by intention. At the end of the passage quoted from Prof. Forbes, it will be seen that he states that he had never mentioned the matter until compelled to do so by some claims of mine for a special mode of working. I do not know what claims are referred to, nor do I know what compulsion he was under; but I do know that in making these statements publicly, without first mentioning the matter to me or to some of my colleagues and giving us an opportunity of expressing our views or giving an explanation, he exhibited a want of courtesy and of ordinary consideration which I venture to think quite exceptional. In the frequent friendly conversations which I have had with him there have been ample opportunities for the discussion of such matters. No doubt he had a right to advise his company as he thought proper; but I maintain that, without the very fullest justification for his statements, he had not a right to come to this Institution and, in the most public manner, utter charges seriously affecting the character and capabilities of a trading company's manufactures. I submit that in his strictures on the synchronising power of my alternators he was absolutely without such justification.

The necessity for correcting a false impression has forced me to take the first opportunity of bringing this matter before the Institution. I regret that Prof. Forbes is abroad, but he will of course have an opportunity of sending on for the *Journal* any observations he may wish to make. It was not my intention to do more than make the above explanation, feeling sure that it would be sufficient to enable the Institution to form a correct judgment on the circumstances; but as I am permitted to occupy more of your time than I expected, I wish to refer to some tests that I have been able to make. It appeared desirable to give the results of actual trials, preferably working one machine as a synchronous motor, and not merely as one of a pair of parallel connected generators. It will be granted that the action of synchronous motors and of parallel alternators is very similar. But with regard to the trials just referred to, it might fairly be argued that as each alternator had a steam-engine behind it, on which it could fall back for assistance, something more is wanted to actually prove that the explanation is applicable to the case of a synchronous motor relying entirely on its own motor properties. I am, therefore, glad to be able to place before you the results of some tests made in the works of the Brush Company.

Some Tests of a 25-Kilowatt Mordey-Victoria Alternator used as a Motor.

This test was carried out by my instructions on February 18, 1891, four months before that witnessed by Prof. Forbes. A 2,000-volt 25-kilowatt alternator was run as a motor, driven by a 37·5-kilowatt generator. The motor drove a dynamo which was loaded until the alternator motor was taking about its full normal current, it being assumed that this represented full power. Separate tests have proved this assumption to be justified. The following readings were taken with a resistance of straight platinoid wire between the machines:

Test A.

Volts. Generator terminals.	Volts. Motor terminals.	Amperes.	Resistance in line. Ohms.
2,340	2,002	13·74	32
2,358	1,932	13	48

The volts of the generator were raised above the motor volts sufficient to supply approximately the line loss. This test was quite satisfactory, and, of course, settled, so far as we were concerned, any question that might at any time arise as to power transmission over long lines by synchronous motors—a matter that was from time to time coming up in connection with proposed installations. As a result, I always considered it quite safe to quote for work up to a line loss of

Digitized by Google

20 per cent. But my attention being recalled to the subject by the extraordinary statements of Prof. Forbes, I took the opportunity, after writing the foregoing explanation, to make some tests having a particular bearing on the details of the question before us. In some respects they are rather wanting in completeness—I was not always able to carry them as far as I wished—but I feel sure that you will approve of my supplementing my explanation by an account of such tests as the facilities at my disposal at the moment rendered possible.

TESTS OF 50-KILOWATT ALTERNATOR AS A MOTOR.

The object of these tests was to ascertain the effect of inserting resistance between two alternators, one of which ran without load as a synchronous motor. It was desired to find—(*a*) what resistance was required to cause the motor to fall out of step; (*b*) how much the current varied, and how it varied; and (*c*) whether any "hunting," or pulsation, was set up. Two similar 2,000-volt 50-kilowatt alternators were used.

Generator.—This was driven by a separate engine capable of working it up to full load. It was run without governor, and controlled by hand at the throttle-valve.

Motor.—This was started and brought up to synchronism by a small direct-current motor, driving by a belt which was thrown off as soon as the large motor was running synchronously. The two machines were excited from a separate dynamo, their fields being in parallel. The E.M.F. at the generator terminals was measured, and the current from armature to armature. The field currents were not measured, nor the E.M.F. at the motor terminals. The generator was excited to give 2,000 volts, and then the motor field was adjusted till the current received by the armature was a minimum. This will be understood from Fig. 2, which is reproduced from a paper on

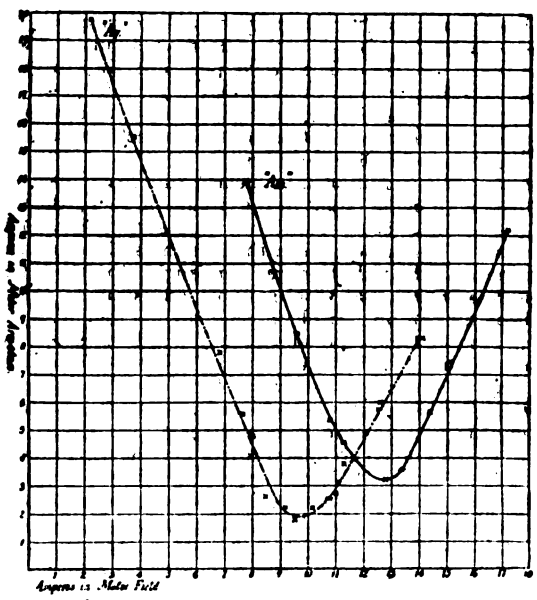


FIG. 2.

"Testing and Working Alternators" I had the honour of reading before this Institution last year. It may be remembered that I showed that there is a well-marked excitation that reduces the armature current to a minimum for any given load, and therefore gives a maximum power factor and maximum efficiency. If the excitation be varied on either side of that value, the armature current taken by the motor rapidly increases. In working a motor it is desirable always to adjust the excitation till the bottom of this V-curve is reached—that is to say, until the armature current is a minimum. In the case before us this current was found to be 1·6 amperes. Having got this, the excitation was not disturbed, and the following readings were taken:

Test B.

Volts at generator terminals.	Current.	Resistance in external circuit between generator and motor.	Remarks.
2,090	1·6	0	Current steady.
,,	1·6	10	,,
,,	1·6	20	,,
,,	1·7	35	,,
,,	3·5	63	,,
,,	3·6	69	Current rather unsteady.
,,	5 3	77	,,
,,	—	90	Current increased rapidly at this point, and the motor slipped quietly out of step.

In the first place, it is to be noted that there was no "hunting," or pulsation. The unsteadiness of the current was not regular. Examining this test with a view to its practical aspects, it will be seen that it fully supports the explanation given at the commencement. Applying to it a similar comparison, we see that, as the alternators were 2,000-volt 50-kilowatt machines, a line proper to these, in order to comply with the Niagara-Buffalo condition of allowing a loss of 3·5 per cent. in transmission, should have a resistance of

$$\frac{2{,}000 \times 3{\cdot}5}{25 \times 100} = 2{\cdot}8\ \omega;$$

and that the resistance of external circuit that would be sufficient to dispose of the whole load of the generator, supposing it to be merely working on that resistance as a load, would be

$$\frac{2{,}000}{25} = 80\ \omega.$$

Exactly as in the case of the trial witnessed by Prof. Forbes, we find that a resistance of about 30 times a reasonable working amount had to be inserted before synchronism was interfered with, and it will be observed that more than 20 ohms had to be inserted before any effect appeared to be produced. But it may be said that the line loss, even with this enormous resistance, is comparatively trifling, as the current is not large, and that there ought to be plenty of power left to keep the motor in step. There is plenty of power, but it cannot be applied to the motor advantageously. The line loss, even with 5·3 amperes and 77 ohms, is only 408 volts and 2,156 watts (I am considering only resistance and current), whereas the generator was capable of supplying 50,000 watts. But it must be remembered that, the E.M.F. of the motor being kept up, it can only receive current under these conditions by letting itself get partly out of phase (and so into a disadvantageous position), and that then every increase of current intensifies the evil by causing a further loss of volts on the line, and therefore a further reduction in the E.M.F. impressed on the motor. How I lowered the E.M.F. of the motor, or increased the E.M.F. of the generator, the line resistance could have been still

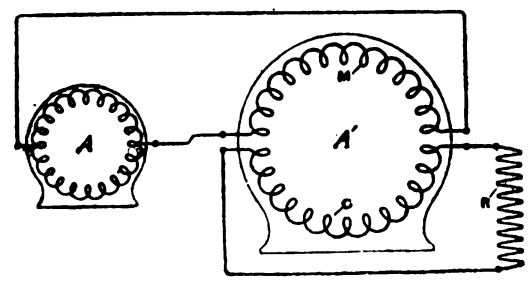

FIG. 3.

further increased without loss of synchronism. Such a change of the relative E.M.F.'s of the motor and of the generator would have allowed current to get into the motor against the lower ordinates of its E.M.F. waves, without the necessity for any serious shifting of phase. If the motor E.M.F. had been lowered in this way the driving current would have increased, and synchronism would have been maintained much longer and through a higher line resistance, and would finally have been lost by the power being wasted in the line, and by "armature reaction" on a weakened field.

Or, again, if the excitation of the motor had been raised, it should be found that it would go out of step with a smaller external resistance than before. This matter is of practical importance, as perhaps others than Prof. Forbes may wish to work through a line 30 times too long, and therefore some tests were made to prove the truth of this explanation.

Test C.—The machines were run under the conditions of the fifth line of the readings given above—that is, with the excitation as before, and with an external resistance of 63 ohms, the current being 3·5 amperes. The excitation of the motor was then increased, probably about 20 per cent. Before there was time to take any reading the motor went out of step. This was satisfactory as proving the correctness of the explanation.

Test D.—Another test was made with the motor acting as a dynamotor in the manner shown in Fig. 3 (also reproduced from last year's paper). One half, M, of the armature winding was used as a motor; the other half, G, as a generator working on a separate circuit, R. In this instance a load of five amperes and 2,000 volts was put on this generator portion, the lowest armature current being obtained with an exciting current of about 11 amperes. The field of this dynamotor was then reduced from 11 to 6 amperes, but it did not show any signs of getting out of step. The driving current rose to 15 or 16 amperes. But on increasing the dynamotor field to 17 amperes it went out of step, the driving current being about 15 amperes. This test is not on all fours with the other, as there is the effect to be considered of the varying load on G, but it is a confirmation in a general way of the explanation.

Digitized by Google

Test E.—A test was then made to find, when working with no appreciable resistance between the machines, whether any "hunting," or pulsation, was set up by varying the excitation of the motor till the armature current rose considerably up either slope of the "V." On decreasing the excitation till the armature current rose from 1·6 to 6 amperes the current became rather unsteady or irregular; the motor evidently getting a little out of step sometimes, and being pulled in by slight rushes of current of very short duration, which probably over-corrected the irregularity, causing the machine to run for an instant without current, or to act as a generator and itself to give current—that is, to act as an electro-mechanical flywheel, converting mechanical to electrical energy, and *vice versâ*. On increasing the excitation again, passing the bottom of the "V," and rising up the opposite slope to the same height (about six amperes), it was found that the current was rather steadier than under the conditions last noted—that is, when the current was about six amperes it was rather more unsteady in a strong field than in a weak field. The explanation of this difference is that with a weak field the motor could receive current during its whole phase; whereas with a strengthened field the E.M.F. waves would be higher than those of the generator, and some want of co-phasal synchronism would be needed to allow current to get in. In neither case was there any "hunting" or regular pulsation of current.

Some Tests of a 25-Kilowatt Alternator used as a Motor.

The motor in this case was arranged to drive a direct-current motor by means of which a load could be put on it that would be quite constant so long as speed was constant. It was desired (*a*) to find the effect of placing in the alternator circuit various amounts of resistance; (*b*) to find the effect on the steadiness. The 25-kilowatt alternator motor was driven by a 50-kilowatt alternator as generator.

Test F.—Motor was run with no load except its own direct-coupled exciter, and the direct-current dynamo, which in this case was run unexcited.

Effect of Reducing Motor Excitation as Resistance in External Circuit was Increased.

A. Generator. Volts.	A. Motor. Volts.	Amperes.	Line resistance.	Remarks.
2,000	2,000	2·23	0	Current varying a little.
1,980	1,900	3·7	0	Current very steady.
2,040	1,900	3·5	65	,,
1,960	1,840	2·0	65	,,
1,950	1,820	2·23	75	,,
1,960	1,800	2·0	85	,,
1,960	1,780	2·23	95	,,
1,960	1,760	2·23	105	,,

We thus see a confirmation of what has been said about steady running being obtained, even with a very large resistance in the circuit, if there is a sufficient difference between volts of generator and motor. This is very common sense, and an experiment to prove it may seem superfluous. The experiment was not carried further, as the resistance used was the greatest available at the moment. This light-load test should be read in connection with the full-load test A.

Test G.—A test was then made with a load on the direct-current dynamo. This load was eight kilowatts, and was constant. Allowing for friction, and various losses outside of itself, the alternator motor was doing between 14 h.p. and 15 h.p.

A. Generator. Volts.	A. Motor. Volts.	Amperes.	Power developed, about h.p.	Resistance.	Remarks.
2,040	2,040	7·0	14·5	0	Current fairly steady.
2,040	1,980	7·3	,,	6	,,
2,060	2,000	7·45	,,	10	,,
2,040	1,900	8·2	,,	25	Current steadier.
2,040	1,740	9·8	,,	35	Current steady.
2,120	1,540	11·0	,,	45	,,

In this is seen the gradual increase of motor current as the motor volts get lower, while steadiness rather improves with the addition of length (or resistance) of line. The test is incomplete, because it was not convenient to put a larger load on, and therefore the motor was not worked up to full power; but it is confirmatory of test A. It is interesting to observe, with regard to this test, that the idle current was very small. For example, the first reading of seven amperes may be divided into 2·25 amperes needed to drive the motor and its exciter, and for friction of the direct-current dynamo (see test F); and into 4·75 amperes for the added load of eight kilowatts. The dynamo gave eight kilowatts, and the motor received about 4·75 amperes × 2,040 volts = 9,690 watts. Allowing for the losses in the two machines, it will be recognised that the transformation was not only very fairly efficient, but that the power factor was evidently high. The relative lowering of the E.M.F. of a synchronous motor is a necessity in order to obtain good results in power transmission over long distances. In this way the necessity for self-adjustment by the motor of the phase relation is avoided, the motor being enabled to work (other qualities permitting) at its most advantageous phase relation. And the other advantages are retained of high power factor (that is, a small idle current) and a high efficiency of generator, motor, and line. By this means it will be found possible to work such motors over very long lines, and with almost any desired line loss. It of course has its counterpart in direct-current power transmission, but there is a difference. In once case the speed varies and the field remains constant; in the other the speed remains constant and the field must be varied. It is not necessary to alter the excitation of a direct-current motor—its speed simply drops or rises until it has got the right E.M.F. With an alternate-current synchronous motor the speed cannot drop. The excitation must be lowered in this case to give the right E.M.F. Failing this, the motor will shift its phase in an endeavour to attain the same result. Of course in the direct-current machine the speed may be kept up by lowering the field.

Some Tests of Two 100-Kilowatt Alternators.

Test H.—By the kindness of the City of London Company, I was enabled to make a trial with two of their 100-kilowatt alternators at Bankside, with the object of finding if, under the ordinary conditions of the station, these machines would work parallel with a considerable resistance between them and their load. For this purpose a load of about 100 kilowatts was put on, and the two alternators were made to supply it through a resistance of 7·5 ohms in the external circuit of each. As this resistance corresponds to 37·5 per cent. line drop at full load, and 18·75 per cent. drop at half load, it is a fairly severe test. It was found that some lamps and a voltmeter placed across the load (a wire resistance) kept perfectly steady. This, of course, was only a half-load test.

Test J.—When full load, or nearly full load, was on both machines, with eight ohms in the circuit of each, there was a quite noticeable, but not at all violent, slow pulsation in the synchroniser lamp direct across the terminals of the alternators; but at the load the pulsation was very slight—barely noticeable. My impression was that with suitable adjustments this would have been quite a practicable arrangement—that is, to feed a lighting system from two alternators parallel, each having a 20 per cent. line loss between it and the load—a condition that is not likely to present itself very often.

Test K.—An attempt was then made to run the two machines parallel, with a load close to one of them, but separated from the other by a line of 16 ohms, corresponding to a line loss of about 40 per cent. The machines did not show any inclination to get out of step, but there was a pulsation of the E.M.F. at the lamps (at the load) of about 4 or 5 per cent. The result of this test, as carried out, was not good enough for lighting; although if time and facilities had allowed, I think it quite likely that it could have been made satisfactory; but there was no pulsation or unsteadiness of a kind that would have interfered in any way with power transmission work. It is a pleasure to me to make my acknowledgments to two assistants, Mr. Stobart and Mr. Foyster, who have ably aided me in connection with the recent tests and experiments, and to Mr. Watson in connection with the tests in 1891.

Some Analogies.

Probably I am not alone in having often found a difficulty in conveying to persons not specially familiar with alternate-current matters, any very clear idea of the kind of action that takes place in parallel working. I would like, therefore, to be allowed to conclude by describing an analogy which I have often found useful in such cases. Everybody knows something of toothed wheels. To explain the relations of two alternators, separately driven, working parallel, imagine two engines driving by spur gearing on to a common shaft. The shaft represents the circuit from which power may be taken; the spurs, or teeth, represent the successive waves of current. The operation of getting into synchronism is understood when one engine is imagined as running at its proper speed geared with the countershaft. To get the second engine to help, it will readily be understood that before being geared with the shaft it must be brought up to such a speed that the spurs of its toothed wheel synchronise with those on the shaft. A synchroniser, or phase-indicator, is the equivalent of a device for showing when the teeth of one wheel are exactly opposite the spaces between the teeth of the other wheel—that is, when they are synchronous. The mechanical process of slipping the two spur wheels together is the equivalent of electrically connecting the alternator and the circuit, and all the effects of doing this switching at the wrong time are easily illustrated by the sudden strain that would be imposed on the teeth. It will now be easy to follow the process of increasing the supply of steam to the engine until it transmits

Digitized by Google

its proper proportion of power to the shaft; as well as the reduction of steam to such a point that the connection of either engine with the shaft (or of alternator with the circuit) can be interrupted at a time when no power is being transmitted from it or to it, and when, in consequence, its withdrawal makes no difference to the remaining engine (or alternator) or to the countershaft (or circuit). The changing of load from one engine to the other is readily understood. Then the difficulties of parallel running may be made clear. Imagine one engine to get an insufficient supply of steam: it will be seen how the other must not only keep the countershaft (and any load) going, but must also drive the other engine. And note that this driven engine (receiving its power from the countershaft) is the analogue of the synchronous motor, and that the fact that the pressure is now not on the front side, but on the rear side, of the teeth, corresponds to the pull on the poles and armature coils being in the opposite direction to what it was as a generator, and that the difference of phase, or angle, between a generator and a motor is illustrated by this change in the relative position of the teeth on spur wheel and shaft. If the teeth of one wheel are exactly midway between those of the other, corresponding to exact co-phasal synchronism, a line drawn through the tip of one bisects the hollow of the other, and driving is possible either way in this position only if there is absolute fit—that is, no lag or lead—no clearance either side. And this is not possible in practice. There is always a lead or a lag, corresponding to similar changes in the relative positions of field and armature in an alternator, as generator and as motor, this change of angle being also conveniently expressed or measured in terms of the space occupied by a pair of teeth or a complete period.

Then it is possible, by this analogy, to get an engine-builder to see what happens when an engine runs at different speeds during parts of each revolution. He will see that if two engines are in use, and one is slowing a little as it goes over its dead centres, while the other is getting steam and quickening a little, the teeth of the former will be bearing with diminished pressure on the teeth of the countershaft, while the latter will be exerting increased pressure. And he will see that, if this difference is considerable, the power may all have to be supplied by one engine, which may even have to drive the other engine as well—that, in short, each engine may in each revolution be alternately a generator and a motor, twice or oftener (according to the number and setting of the cranks). It will not be difficult to explain the pulsations of synchronising current transmitted through the circuit between the two alternators by the analogy of the impulses transmitted from one engine to another through the countershaft. He will also understand why, if the engines have this defect, this interchange of power will not take place, and will not be required, if he so arranges matters that the connection is made at a time when the engines (supposing them arranged to run at the same speed) are in the same part of their stroke; but in this case, as the engines cannot correct each other's irregularities, the speed of the countershaft may have an objectionable want of evenness of running, affecting any machinery driven from the countershaft—that this difference will be less on the driven machinery if it is driven by belting, and therefore not necessarily synchronous, than if it is driven by spur gearing, and so forced to run at the same speed.

I will not stop to do more than suggest the comparisons that may usefully be drawn between weight of flywheel and of electromagnetic inertia or self-induction as illustrating the effects in steadying the running of all shafts or circuits. But I cannot resist the temptation to show that, as with alternators in parallel the very rapid interchanges of power take place with scarcely perceptible resistance—that is, frictional—losses, it is conceivable that two such machines and engines will take less steam to drive them than if they are dividing the same load between them on separate circuits. That this increase in efficiency is a fact has been shown by actual tests, which I hope later on will be placed before you. Then the analogy may be carried further, and an understanding may be imparted of the difference in the synchronising abilities of various alternators. To do this it is necessary to add to the analogy of spur gearing the idea of that gearing having teeth of various degrees of stiffness or rigidity, varying all the way from phosphor bronze to yielding elastic material such as soft rubber. The former may be compared to the alternators having unyielding fields and small armature reaction; the latter to machines having poles the magnetism of which gives way, more or less, under pressure. It will, no doubt, be difficult to get the uninitiated to grasp the idea of a tuft of lines of magnetic force from a pole-piece acting, through air, on a copper wire carrying a current as corresponding to the material teeth of spur wheels geared together; but it is at least worth the attempt, and the result is usually better than the antecedent chaos.

Having conveyed this idea of various degrees of rigidity of teeth as the equivalent of the various degrees of synchronising efforts of which different alternators are capable, the next step is to explain why with alternators having magnetic teeth of the gelatinous variety it is possible to put them into parallel (or to gear them) when they are unsynchronous, without anything happening except a more or less complete temporary flattening of the teeth (or alternations) of both machines, corresponding to a temporary cessation of useful effort, until they have gradually worked themselves into phase. And it will be understood why with such machines any sudden alterations or strains should be avoided as likely to result in the bending down of the teeth, and loss of synchronism. On the other hand, it will be seen that, if the machines have strong and unyielding teeth (or powerful synchronising qualities), they will make a prodigious effort to keep in step whatever happens. This analogy affords an explanation of the difference in the way in which the synchronising current circulates between alternators of the two kinds. With spur wheels of the strong type it will be seen that any transfer of power will be immediate and prompt, the correcting impulses being transmitted with decision and sharpness, the lagging or yielding permitted being only that due to the space between the teeth. This corresponds with the short sharp impulses of synchronising current between two alternators of one type; while the slow and sluggish impulses of current between two alternators of the weak field type is understood by imagining what would happen with an attempted interchange of power between the two engines geared to a shaft by teeth of some yielding material.

A further analogy and I have done, to show those who are at all familiar with the mechanics of spur gearing how unnecessary it ought to be, so far as the machines are concerned, to reduce the number of magnetic teeth, or periods, in order to get satisfactory and smooth driving, either singly or parallel. It is only in cases where the electrical spur wheels are so designed that the teeth cannot get in, that a small number of periods can be of any service (so far as the machinery is concerned). Steady and smooth driving is rather to be sought in the other direction.

DISCUSSION.

Mr. Raworth, who opened the discussion, said that the Institution was dependent upon Mr. Mordey for experimental facts relating to the working of alternators, though many members came forward with theories. This was probably owing to his exceptional facilities at the Brush Company's works. He considered that other companies should be equally generous to their employés and afford them opportunities for bringing forward information to the Institution. Prof. Forbes had discovered a mare's nest, and Mr. Mordey had explained it away; but he had not got quite to the bottom of it. Every governor "hunted," and that would be the case until they could get rid of friction. The same results as Prof. Forbes complained of would have occurred had two continuous-current machines been employed. It was nothing in the world but common mechanical effect.

Mr. Sparkes stated that the principal difficulty was to secure suitable steam engines. Compound engines were more satisfactory than single-cylinder engines.

Mr. Kapp congratulated the author on his exceedingly happy analogies, but he had contrasted spur wheels with hard teeth and with flexible teeth to the disadvantage of the latter, and suggested that flexibility conveyed the idea of weakness. There was, however, no reason why flexible teeth should not be equally strong. The flexible teeth yielded until they attained force. Mr. Mordey had hardly done himself justice in his experiments. Had he put on a mechanical load of, say, 50 kilowatts, such as would occur in a transmission installation, the machines would have dropped out of step far sooner. If they had a long line and could not afford much copper, then it was advisable to have the motor at lower excitation than the generator, but they had it in their power to raise the voltage and have little line loss. Then this would not be the case. A margin of power was required where heavy machinery was suddenly set to work, and then the motor should be excited higher than the generator. At Bristol, where he and Mr. Preece had laid out an installation, an even torque was necessary, and engines with three cranks were found very satisfatory.

Prof. Silvanus Thompson remarked that it was desirable to have further discussion from other makers of alternators in regard to running them on a large scale, especially in the case of the transmission of power along a line. There was no doubt that a special motor would have to be designed to work at the end of the line. He thought that the author deserved thanks for the analogies referring to gearing. There were other ways of synchronising than those already mentioned. There was the acoustic synchroniser, which howled all day and gave information to the ear instead of to the eye. Had no one any experience of optical synchronising attached to the machines? At Rome the alternators were set in a line, and one could look through one machine on to another and see when the machines were synchronised by observing the rotating of the magnets of one machine across those of another. It was quite possible that some optical synchroniser might be found better than the method of using lamps or acoustic appliances. He asked whether any of them had any information on the use of a common steam supply to the engines driving the machines to be put in parallel or which were running in parallel. It was desirable that an opinion, or, rather an actual experience, should be given under different circumstances with different types of engines, types of governors, and of alternators, especially as to the conditions under which the machines were run most satisfactorily in parallel.

The President adjourned the discussion to the 29th inst.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" *can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—*

	3 months	6 months	12 months
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements should be made payable to C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."*

BOUND VOLUMES.

Vol. XII. of new series of "THE ELECTRICAL ENGINEER" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

THE GUILEFUL PATENTEE.

Twelve or fourteen years ago a number of men obtained patents for which they have since obtained large sums of money, either in the lump from companies formed for the working of the patents or in the shape of royalties. These valuable patents can almost be counted upon the fingers, though the total number of patents taken out may number hundreds, perhaps thousands. As soon as a new departure is made in any direction, scores of professional inventors set themselves to work to see if they cannot possibly devise something that will enable them to get round the original patent. There is another class of men whose conduct we wish to bring into discussion—the small capitalist. Thousands of men are in great haste to get richer. Many have been long years in business, and by care, intelligence, and industry have saved a competency and retired. These men, unfortunately, seem easiest bitten with the mania for increasing their store by dabbling in patents. Periodically, some such person invites our attention and asks our advice, having financed the impecunious inventor to the extent of hundreds, sometimes thousands of pounds. There is no remedy. In no single case have we ever found the invention worth a moment's consideration, or having the commercial value of a brass farthing. Those who advanced the money are often ruined, or reduced to very straitened circumstances. Inventors, almost without exception, are favoured with the gift of the gab. Many of them believe anything they want to believe, and in flowing, flowery language tell their dupes of the immense sums to be realised and the revolution to existing industry when their invention is perfected and put upon the market. Unfortunately, perfection is like the millennium — always in the distance. Money gets tight before the invention is ripe for use. This is a state of things it is desirable should no longer continue. The glamour of the early eighties dies hard. Men are still duped. Almost every week advertisements appear in the daily papers for pecuniary assistance to exploit some electrical invention. This is when the inventor has ruined his dupes obtained privately, or when he cannot obtain such dupes. There is another class of inventor or exploiter, forming a fairly large colony in London, comprised of many nationalities—English, French, German, and American—each member of which haunts the City, calls upon every company promoter with an invention for the exploitation of which he proposes a company should be formed. Thank goodness, company-mongering has of late been somewhat dead. But if there should be a revival, we have no doubt attempts will be made to float companies to run some of these woe-begone inventions. It must be understood that a company promoter has but one object—to make money. The intrinsic value of the patent is nothing to him, provided he can get sufficient satisfactory reports—which again is purely a question of money—and make up a prospectus that shall enable him to victimise the public. After he has got his promotion money, so far as he is concerned, the deluge may come as quickly as it likes.

Digitized by Google

In our opinion, the public, whether asked privately or publicly, should be exceedingly chary in opening its pockets for the exploitation of patents. We are perfectly certain there are firms and companies existing managed by level-headed men who have a comprehensive knowledge of what is wanted. These men are always ready and willing to examine carefully the value of any patent submitted to them. They are only too glad to obtain an improvement that gives them a practical monopoly in a particular direction, and assists them in the competition against rival firms. The public is not required to waste its money, and may take it for granted that when asked to subscribe to syndicates or companies for the purpose of purchasing patents, the patents offered are almost wholly or quite valueless. We have called attention to this subject at the present juncture because there is a kind of revival among these inventors, and men are being asked largely in private and in public to invest in patents that are of the most trumpery character. Money obtained in this way ought to land those who get the money in the criminal dock for getting money under false pretences. However, the law does not recognise this as a crime; so all that can be done is to warn capitalists against the charming of the patentee who has patents for sale.

GOODWILL AND CONVERSION.

There is, perhaps, no great advantage in the consideration by lay minds of intricate legal points, though very often questions of equity are more easily decided by the application of a little sound common sense than by a million arguments from learned counsel. When it comes to interpreting Acts of Parliament, the task is even harder, and of considerably less use, for ordinary minds are not supposed capable of suggesting facts or consequences.

It may be, therefore, complete waste of time to discuss the question of what sums ought to be paid as "the then value" to tramway companies by local authorities when the latter desire to exercise their right of purchase of lines and equipment under the Tramways Act of 1870. Yet, owing to the importance of the final decision (whenever it may be given by the House of Lords as a last court of appeal) to the electrical industry, we deem it worth while calling attention to what may be the probable consequences of construing the words of the Act in one way or the other.

If "the then value" is held finally to mean so many years' purchase of the tramway company's business—that is, must include goodwill, over and above the estimated worth of the plant and equipment—then there is little doubt but that few municipalities or local authorities will exercise their rights of purchase, and take over the lines when the opportunity occurs. At the present time there are hardly any tramway companies which possess a financial standing sufficient to enable them to convert their system of working so as to employ electricity as the motive power, and the consequence will be that electric traction must suffer a severe set back. On the other hand, if the municipal authorities are enabled to purchase the lines upon reasonable, if not highly favourable, terms, they can borrow money at such low rates as to make it quite easy to adopt electric traction by equipping the lines with overhead wires and erecting generating stations, etc., on a large scale.

We do not expect shareholders in tramway companies to undergo financial martyrdom for the sake of electric traction; but there ought to be some middle and fair way out of the difficulty. In the case of electric lighting schemes, the maximum time allowed the promoters in which to make a reasonable profit is double the limit given to the tramway companies for the same purpose, but specific mention is made by Parliament that goodwill or profits, past and future, must not in such a case be taken into account. When the consequences to electric traction may prove so serious, it is much to be regretted that the two classes of undertakings cannot be in some way put upon the same level. We hope, at any rate, to see efforts made in this direction.

The question of municipalities *working* the tramway lines does not, of course, enter into the dispute. Most people seem agreed upon the advisability of local authorities *owning*, and therefore being allowed to purchase, undertakings of a public nature such as gas and water supply, electric lighting, and tramways, etc. The point seems to turn upon what shall be the price which local authorities ought to pay for undertakings already established (whether they intend to work or to sub-let them), and we think the decision of this question will have a very important bearing upon the development of electric traction.

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

RUNNING ALTERNATORS IN PARALLEL.

SIR,—Mr. Proctor's letter, as most of the information given on the above subject, deals only with the *possibility* of running alternators in parallel, but not with what affects central-station engineers most—viz., *practicability*. We all know that alternators *can* be run in parallel—but what is gained by doing so? It is an acknowledged fact that it takes some time (and this time is most uncertain, varying from half-a-minute to four minutes or more) to get the machines properly synchronised before they can be switched on to the mains. In the case of a breakdown, in which, say, one machine is incapacitated and has to be switched out, this time is most valuable, as all the while the other machines are overloaded, or should be if parallel running is used economically and not with a big margin of safety. Again, supposing a good number of alternators are running in parallel on one pair of mains, we get a repetition of the recent Bankside breakdown.

We can run our machines in parallel in Bath, but find the system of having many circuits, any of which can be switched separately on to any machine, much more reliable. We can thus load up our machines to their full capacity, and in case of a breakdown another machine is run up to speed far more quickly than it takes to synchronise.

Some of the new stations are so designed that parallel running is forced upon the engineers, others are arranged to run either in parallel or separate circuits on separate machines (like the Bath station), and others only on the separate circuit system. I have noticed that when the engineer has the option of using either system, he almost invariably uses the separate circuit system; and when he only has the latter system, he is in no hurry to adopt parallel

Digitized by Google

running. And I firmly believe that the engineers in charge of stations in which their alternators can *only* be run in parallel would prefer, if they had to choose, either of the other systems rather than be bound to the one. But engineers in charge do not, as a rule, design their own stations, and central-station designers do not have the responsibility of a heavy winter's run.

Until some reliable means of automatically cutting out machines in cases of breakdowns, as used with continuous current, and a more rapid and satisfactory system of synchronising is discovered, I cannot see that parallel running for alternators will ever be a thorough success.—

Yours, etc., G. F. METZGER,
Chief Engineer, Bath Electric Light Company.
March 7, 1894.

REVIEWS.

Electricity in the Service of Man. G. R. WORMALL, D.Sc., M.A. From the German of Dr. A. R. von Urbanitzky. Revised and enlarged by Prof. R. M. Walmsley, D.Sc., F.R.S.E. With more than 950 illustrations. Cassell and Co.

The new edition of this book differs considerably from the old. Much irrelevant matter has been displaced, and large additions have been made. We do not agree with many of the scientific explanations given. They are wrong; but, as a matter of fact, in this book science may be ignored, and the notice of it restricted to descriptive matter only. If we were asked to define the aim of the book we should say it was intended to be a descriptive encyclopædia of applied electricity. The author and editor seem to have desired to bring within the covers of one book a correct, graphic, if not lengthy, description of every piece of modern electrical apparatus that has been devised and come into use, whether such use is restricted or almost universal. Further, description is given of much of the apparatus now becoming historical, when that apparatus has formed a step in the advance from the earliest attempts to that at present in use. Indeed, in some cases so anxious has been the editor to miss nothing that he has described in his text apparatus that has no more to do with electricity than it has with the manufacture of sugar. The editor knows this, and why, thus knowing, he includes the phonograph in an electrical treatise is beyond comprehension. With the exception of these minor blemishes, the present editor has produced a book which is by far the best of its kind. The information he has collected and given is immense. The descriptions are clear and accurate, the illustrations good and ample, and altogether the book is one that should be exceedingly valuable to all who wish to obtain a good general idea of the various applications of electricity. It is intended to be a popular book, and it admirably fulfils that intent.

The Inventions, Researches, and Writings of Nikola Tesla, with Special Reference to his Work in Polyphase Currents and High-Potential Lighting. By THOMAS COMMERFORD MARTIN. *The Electrical Engineer*, New York.

Whatever we may think of the heroic action of the soldier who gains the Victoria Cross, there is little doubt but that all scientific electricians will place the heroism of Nikola Tesla upon a higher pedestal. The man—no matter the reasoning which led him to it—who first hazarded the action of enormously high-potential currents could not help being heroic. Scientific heroism which leads doctor or physicist to test in his own person the value of a theory is to our mind a higher form of heroism than mere physical bravery. And Nikola Tesla stands pre-eminent in the electrical world as having himself tested his theories. Mr. Martin has been very active in collecting all the information that has appeared about Tesla's work. Our readers are not unfamiliar with much that he has done, but they will find it more completely set forth in the pages of this volume. The editor acknowledges that a large amount of the practical work carried out by Mr. Tesla is as yet unpublished. This of course is only what we should expect. Mr. Tesla wants to apply his theories, and is experimenting for that purpose. These experiments are not for the world till the author's chosen time. We are all waiting for future revelations, and we can only say that Mr. Tesla's published results have already placed him high among both theorists and practical men, and that Mr. Martin has produced a volume so far exhaustive, worthy of the theme he discusses.

THE PATIN AND LEVAVASSEUR MACHINE.*

The machine we are about to describe is composed mainly of the following parts: (1) an inductive system composed of an iron ring with eight poles alternately positive and negative, projecting inwardly, and a star-shaped interior core, upon the radial segments of which are mounted the exciting coils so as to present poles of opposite sign to those on the ring; (2) an armature composed of 10 flat coils, or two more coils than there are poles; and (3) a 40-bar commutator, to which the armature coils are connected. Fig. 1 shows the connections between the armature coils (which rotate, as shown, between the inner and outer rings of poles) and the commutator.

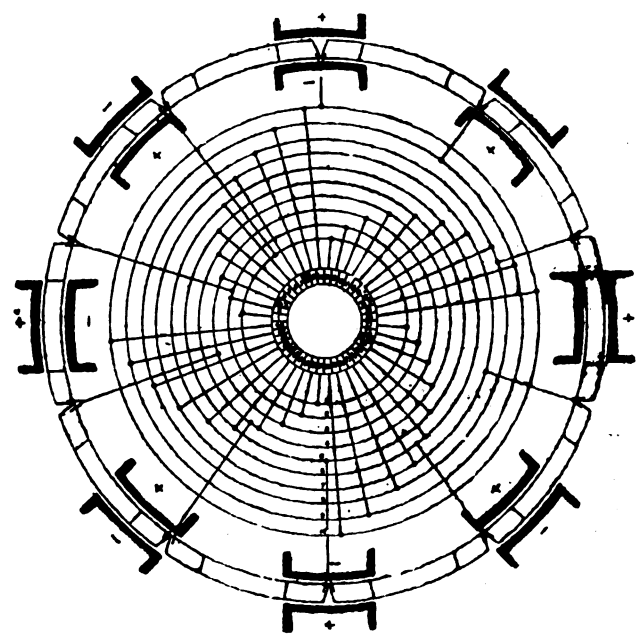

FIG. 1.

The core and poles of the field magnets are built up of iron plates. The armature is made up of 10 coils, each in shape of a flat elongated oval, and are composed of copper ribbon insulated with fibre; after being coated with shellac they are bent, so as to lie flat upon the circumference of an insulated metal drum parallel with the dynamo axle, to which the drum is keyed by means of a spider. They are bolted upon the drum at one end only. The other ends of the coils project from the drum parallel with its axle, the overhang being enough to allow the coils to be rotated in the narrow annular space between the inner and outer poles. They form a closed continuous circuit, so that if the circuit is interrupted at any point while the machine is running the coils become solenoids, presenting alternate positive and negative poles. From ten points of junction the coils are connected by the same number of wires with ten different insulated rings. The bars 1, 11, 21, 31 are connected with ring 1; bars 2, 12, 22, 32 are connected with ring 2, and so on, up to bars 10, 20, 30, and 40, which latter is joined to ring 10. The machine chosen for illustration is an eight-pole and ten-coil machine, but so long as the same principle is preserved these numbers may be increased.

When the dynamo is running as a constant-current generating machine, eight brushes may be arranged round the commutator at a distance of five bars from each other, and connected in parallel in pairs. Many other combinations may be made with two or more brushes. Ordinarily, the machine has only two brushes disposed on the commutator—5, 15, 25, or even 35 bars apart. Suppose, for instance, they were 15 bars apart. If the machine is generating current, the brushes should be in contact with

* Abstracted from *L'Electricien*.

Digitized by Google

the bars X and Y (shown in Fig. 1 at segments 3 and 18); if it is running as a continuous or alternate-current motor, the brushes should be in contact with bars Z and U, or segments 8 and 23.

Let us now consider a machine (Fig. 2) with four pole-pieces and six armature coils. Careful attention should be paid to the four poles, the six coils, and the twelve bars of the commutator. In the position shown in the figure, coil 1 is in front of pole 1 and coil 4 in front of pole 3. One rotation—clockwise — equal to $\frac{2\pi}{12}$, corresponding to the angular opening of a segment of the commutator, will bring coil 2 in front of pole 2, and coil 5 in front of pole 4. A second rotation of $\frac{2\pi}{12}$ brings coil 3 in front of pole 3, and coil 6 in front of pole 1. It will also be seen that for the coincidence of a pole with a coil a rotation is required of $4 \times \frac{2\pi}{12}$ or $\frac{2\pi}{3}$, and that for each complete revolution of the machine this coincidence must occur three times.

What, it may be asked, are the relations between the movement of this coincidence and the number of poles and coils?

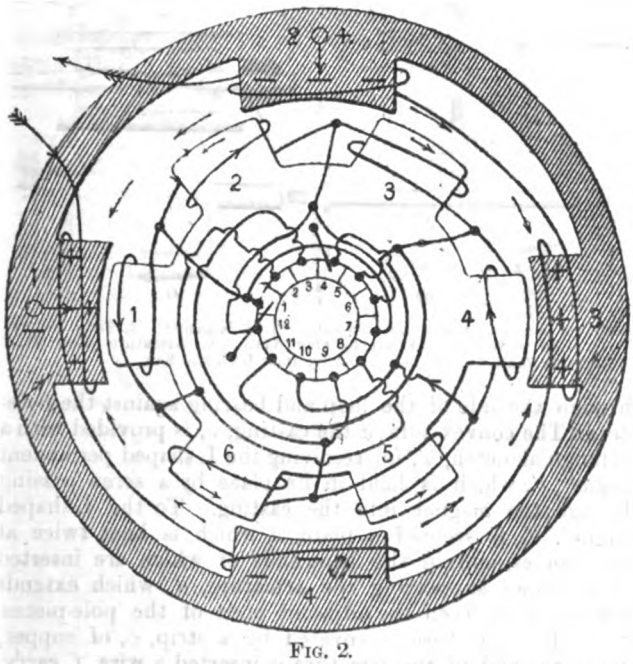

FIG. 2.

Let p be the number of field coils or poles, and $p+2$ the number of armature coils. We know that for an angle equal to $\frac{2\pi}{\frac{p(p+2)}{2}}$ the coincidence of coil and pole will advance one pole. Consequently, it will move once round for a rotation of $p \frac{2\pi}{\frac{p(p+2)}{2}} = \frac{2\pi}{\frac{p+2}{2}}$. That is to say, the coincidence travels once round for an angle of advance of $\frac{2\pi}{12}$ if there are 24 coils and 22 poles.

Having so far explained the importance of this coinciding of coil with pole, its rotary movement and relation to the number of coils and poles, it may be added that at each instant all the coils to the right and within the limits of a semicircle—moving in the same way as the hands of a watch—furnish currents of the same sign, whose E.M.F.'s are superadded to one another. The same may, of course, be said of the coils moving in the semicircle to the left. If two collectors are mounted so as to coincide in position with what we have called the "coincidence" itself—*i.e.*, coil and pole coming opposite one another—and follow the same course, moving with the same speed, a direct current may be collected from them. The coils to the right and left of such "coincidence" are practically connected in two parallels, and may be compared with the two halves of the armature of a continuous-current dynamo.

In the four-pole and six-coil machine we have seen that the angle of rotation which advanced the coincidence of one pole was $\frac{2\pi}{12}$, and that, generally speaking, p being the number of poles, and $p+2$ the number of coils, that angle is equal to $\frac{2\pi}{\frac{p(p+2)}{2}}$. It is easily understood that if the segments of the commutator preserve a relative angle, the brushes will always follow the course of the coincidence. The number of segments is given then by the expression $\frac{p(p+2)}{2}$. When the coincidence makes one turn, the brush passes p segments, and the coincidence makes one turn for an angular displacement of $\frac{2\pi}{\frac{p+2}{2}}$, and p turns for a complete revolution of the machine.

The coils furnishing positive current are $\frac{p+2}{2}$ in number, and an equal number of coils supply negative current. The segments are numbered from left to right. They are connected to the armature coils from right to left, and in this way $p+2$ coils are joined to $p+2$ bars of the commutator. The $(p+3)$rd bar is joined to the first, and so on; therefore $\frac{p}{2}$ bars are in connection with each coil.

The brushes are adjusted in such manner that they collect from the coils in coincidence. As the machine rotates, it will be seen that, in spite of the coincidence movement, the brushes always remain in a relatively constant position with the coinciding coils. In effect, the angle of rotation representing one turn of the coincidence includes p segments.

HOW TO MAKE A TELEPHONE CALL.

No telephone line is complete without a signal of some kind which will serve to attract the attention of a person in the vicinity of the instrument. A battery call answers very well for short distances, but for a distance of from one to twelve miles or more the battery has been found impracticable, and the magneto call is generally employed. This instrument, not only serves a good purpose in connection with the telephone, but it answers very well indeed for general signalling purposes. It is always ready for action, and does not involve the care of a battery.

The pole-pieces, A A′, between which the armature, B, revolves, are formed of soft grey cast iron, with ears, *a a*, at the top and the ears, *b*, at the bottom, separated by bars, C C′, of non-magnetic material, such as vulcanised fibre, hard rubber, or they may be made from hard wood, well varnished or saturated with paraffin to prevent them from shrinking or swelling. The pole-pieces, A′ A′, are clamped to the bars, C C′, before they are bored out. They are bored out to loosely fit the armature, B. The pole-pieces are provided with flanges, *c*, which rest upon the bottom of the casing, and are drilled to receive screws, *d*, by means of which the magnet is secured in place in the casing. In the pole-pieces, A A′, above the ears *b* are drilled and tapped holes, *e*, for receiviag the studs, *f*, by which the horseshoe magnets are secured to the pole-pieces. The studs, *f*, are drilled for receiving keys, *g*, by which the magnets are clamped in place.

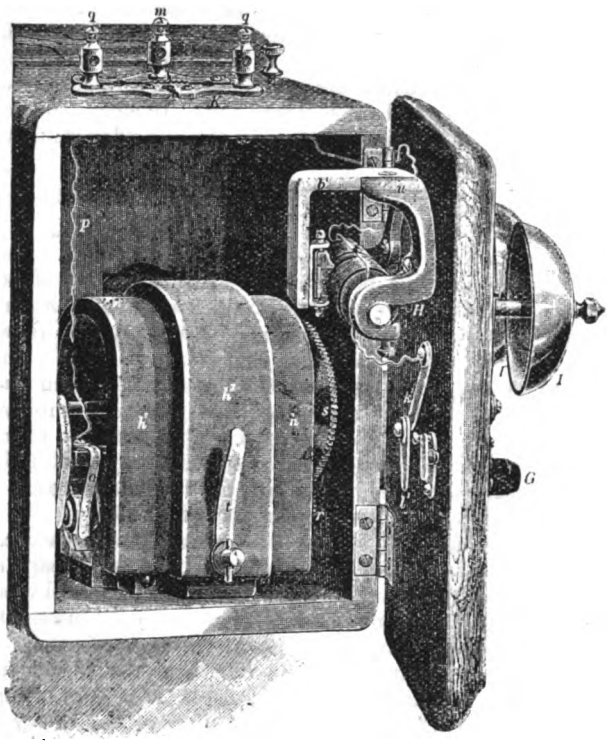
The compound magnet, D, is composed of three flat steel bars, forming U-shaped magnets, *h*, *h′*, h^2, with the space between the poles adapted to receive the pole-pieces, A A′. The magnet h^2 fits over the adjoining edges of the magnets *h h′*, and the three magnets are drilled to receive the studs, *f*, which extend through the magnets and into the pole-pieces, the parts being clamped together by keys driven through the holes in the studs, as shown in the perspective view.

The armature, B, is the well-known H-type of Siemens, made of soft grey cast iron, the shaft, *i*, being cast integrally with the body of the armature. The part, *j*, which receives the wire is narrower and shorter than the polar extremities of the armature. The armature is turned

Digitized by Google

so that its convex sides will revolve very near but not in contact with the pole-pieces. The shaft at the ends of the armature is turned, and to one end is fitted a sleeve, *k*, of insulating material (vulcanised fibre or hard rubber), on which is placed a brass ring, *l*. In the inner side of the metallic ring, *l*, is inserted a stud, *n*, to which is soldered one terminal of the armature coil, the other terminal of which is soldered to a screw, *n*, inserted in the shaft, *i*. The armature is wound in the same manner as an electro-magnet, the wire being carried around one arm of the armature until one-half of the wire is in place. It is then carried across the central portion of the armature and wound upon the other arm of the armature. The wire used is No. 34 silk-covered wire, there being about 1½oz. of wire upon the armature, or enough to give it a resistance of 200 ohms.

To the bar C is secured a brass plate, E, by means of screws which pass through the plate and into the bar. In the plate, E, opposite the centre of the bore of the pole-pieces, there is a bearing for one end of the shaft of the armature, and in the opposite or upper end of the brass plate, E, there is a bearing for the driving shaft, F. To the opposite end of the bar C and to the bar C′ is secured a plate, E′, which is also provided with bearings for the armature shaft and for the driving shaft. To the bar C is secured a curved spring, *o*, which bears upon the insulated ring, *l*, and this spring is connected by a wire, *p*, with a binding post, *q*, at the top of the casing.

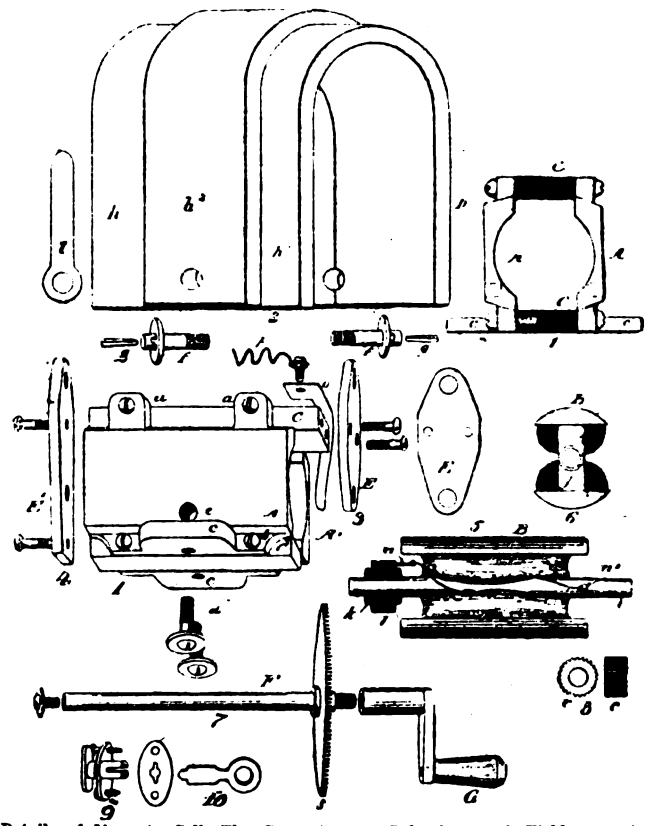


Magneto Telephone Call.

Upon the end of the armature shaft, *i*, outside the plate E′ is placed a pinnion, *r*, and upon the shaft, F, is placed a spur wheel, *s*, which engages the pinion, *r*. The shaft, F, is held in place in the machine by a screw inserted in the end of the shaft, and a washer held by the screw against the end of the shaft and bearing against the plate E. The crank, C, by which the shaft, F, is turned, is screwed on to the end of the shaft through an aperture in the side of the casing. On the stud, *f*, projecting through the front of the magnet is placed a contact spring, *t*, which is clamped by the key which holds the magnet in place.

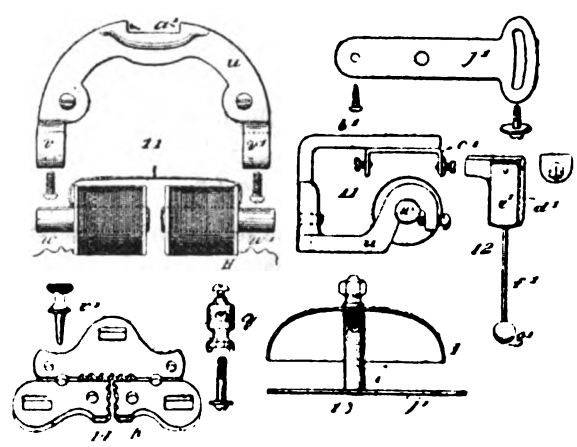
The mechanism thus described comprises the magneto generator which generates the alternating current required for operating the magneto bell. The machine is held in place in the casing by the screws, *d*, as already described, and the back of the casing is cut away to let the magnet h^2 into the back, thus economising room. To the cover of the casing is attached the magneto bell, H, the magnet and armature of which are placed within the door, while the bells are placed on the outside of the door, the hammer extending through the door and between the bells.

The body of the magneto call consists of a curved casting, *u*, which is secured to the inner face of the door and provided with loops, *v v′*, for receiving the soft iron pole pieces, *w w′*, of the bell magnet. These pole-pieces are held in place in the loops, *v v′*, by screws passing



Details of Magneto Call—The Generator.—1. Pole-pieces. 2. Field magnet. 3, 4. End plates. 5. Armature, Side View. 6. Armature, End View. 7. Driving Shaft. 8. Pinion. 9 and 10. Door Lock and Key.

through the side of the loop and bearing against the pole-piece. The convex side of the casting, *u*, is provided with a rectangular notch, *a′*, for receiving the L-shaped permanent magnet, *b′*, which is held in its place by a screw passing through the magnet into the casting. To the L-shaped magnet, *b′*, is secured a plate, *c*, which is bent twice at right angles, and in the bent ends of which are inserted pivot screws supporting the armature, *d*, which extends downward between the adjacent ends of the pole-pieces, *w w′*. The armature is covered by a strip, *e′*, of copper, and in the end of the armature is inserted a wire, *f*, carrying at its extremity a bell hammer, *g′*. To the outer surface



Details of Magneto Call—The Bell.—11. Call Magnet. 12. Armature. 13. Bell. 14. Lightning Arrester and Cut-out.

of the door, and on opposite sides of the bell hammer, are supported two bells, I, by studs, *i′*, projecting from adjustable plates, *j′*, pivoted to the door at one end and provided with a curved slot at the opposite end for receiving a clamping screw, which passes through the slot and into the door. By means of this device the bells may be adjusted so that each will receive a stroke of the same power from the bell hammer, *g′*.

Digitized by Google

The spools on the pole-pieces, *w w'*, contain about 1½oz. of No. 34 silk-covered copper wire. They are wound in the same direction, and the inside ends are connected together. The outer end of one spool is connected with the upper hinge of the casing, which, in turn, is connected with the binding post, *q'*; the outer end of the remaining spool is connected with a strip, *k'*, of copper attached to the door and connected with a plate, *l'*, which comes into contact with the spring, *t*, when the door of the casing is closed.

On the top of the casing there is a plug switch, which also answers as a lightning arrester. The rear plate of the switch is provided with the binding post, *m*, which is connected with the ground. The binding posts, *q q'*, receive the ends of the line wire, the connections being made as shown in the article on the telephone in *Scientific American*, February 3.

When the call is placed at the end of the line, the call-box is grounded by inserting the plug, *r*, between the rear or ground plate and the front plate that is not connected with a line wire. When it is desired to cut the call-box out of the line, the plug is inserted in the circular space between the two front plates, the current passing from one end of the line through one of the binding posts and plate to the plug, the other plate and binding post to the other portion of the line. When the armature, B, is turned by revolving the crank, G, opposite ends are alternately presented to opposite poles, the consequence being that the rapid changes of magnetism in the armature induce alternate pulsations in the winding of the armature which operate the polarised bell of the instrument, also the polarised bell of the distant instrument, both being normally in the circuit.

While talking over the line, it is important to cut out the magnet on account of its resistance, and while signalling over long distances the signals are more effective if the telephones are cut out of the line.—*Scientific American.*

HOW TO MAKE A TELEPHONE.

The following description and cuts of a telephone very simple to make we borrow from the *Electrical World*, which states that it will give excellent results on lines up to five or ten miles in length, when used both as a receiver and transmitter. If used in connection with a transmitter, it will answer for any length of line. If the line is to be constructed in close proximity to electric railway or light wires, it should be made a metallic circuit, but elsewhere a grounded circuit will answer just as well.

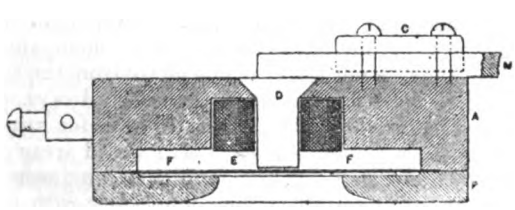


FIG. 1.

The material required for a set consisting of two telephones, one for each end of the line, is as follows: 1oz. No. 36 silk-covered magnet wire; two horseshoe magnets, 4in.; two flat-head stove bolts, ¼in. diameter and 1½in. to 2in. long; a piece of photographer's tintype large enough to cut from it two round diaphragms 2½in. in diameter; four small wood screw binding posts; 12 flat-head brass screws ¾in. long. Use well-seasoned mahogany, or any hard wood, about ⅞in. to 1in. thick for the main case, and for the cover that ¼in. or ⅜in. in thickness is best. The pieces of wood should be larger than the dimensions given, and if marked and bored before sawing to the size desired, there will be less likelihood of splitting.

From Fig. 1 the dimensions for the holes in the wood can be obtained. The 2½in. space under the diaphragm, F, can be bored with an extension bit or marked out with a compass and cut out with a chisel. The 1in. hole should be bored with a bit which has no lip, in order to leave strength sufficient for counter-sinking the head of the stove bolts. The depression in the lid need not be as deep as shown, but merely enough to clear the diaphragm. The stove bolt should be cut to a length a little longer than necessary and then carefully filed and fitted by trial, so that when in place it will just clear the diaphragm.

For the wire a spool should be made of cardboard to fit the bolt and central hole neatly; the spool with wire, E, is wrongly shaded in the cut.

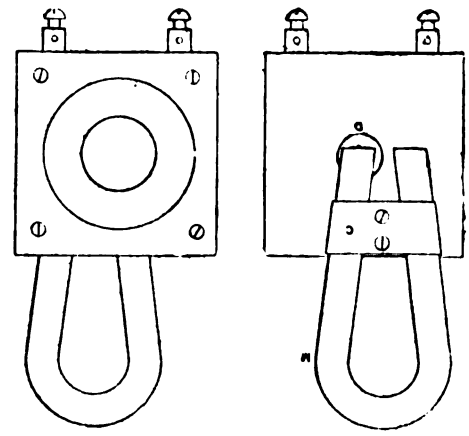

FIG. 2.

The magnet is held in place, with one pole over the bolt head, by a piece of wood, as shown in Fig. 2, the part between the legs of the magnet just clearing the bottom when the screws are home. The ends of the wire are brought to the binding posts through two small holes bored in the wood. Magneto bells are the best, and, in the end, the cheapest for use as call bells in connection with the telephone.

THE ELECTRIC LIGHTING OF SORTING-TENDERS.

A paper was recently read before the Electrotechnical Society of Berlin by Herr C. Grawinkel, one of the German Post Office officials, on the electric lighting of postal sorting tenders on railways in Germany, a subject to which we have previously briefly referred.

The author first gave statistics showing the immense amount of work done in such tenders. An important point in connection with the tenders was the lighting arrangements, which should cause as little increase of the temperature as possible, should not make the air foul, and should not be liable to cause risk of fire. Since 1875 gas lighting had taken the place of oil, and was better, but it caused heat, and the air was affected by the products of combustion; the light was not steady, and though danger of fire was not much to be feared, it was nevertheless possible. The attention of the authorities was consequently given some time ago to the question of lighting the tenders electrically. The lighting of a single wagon in a train did not offer the same difficulties as lighting a whole train, and the improvements in accumulators within recent years induced the Post Office to make a trial. Favourable results were obtained in tests made with accumulators furnished by Herr Böse, of Berlin, and in the middle of May last an experiment was made with them between Berlin and Frankfort-on-the-Maine. A battery of 16 cells was employed, supplying current to eight 12-c.p. incandescent lamps. The result was successful, and it was determined to carry out further experiments on other tenders. These are run on the night expresses between Berlin and Frankfort, Berlin and Eydtkuhnen, Berlin and Leipzig, Berlin and Dresden, Berlin and Alexandrowo, Berlin and Cologne, and Berlin and Breslau.

Batteries.—The batteries for long journeys consist of two sets each of 16 cells. Each cell contains five positive and six negative plates. Each set of four cells is placed in a wooden box, protection of the glass cell against jolting being obtained by coverings of "colophonium." Even if the glass cracks the fluid does not escape through the surrounding material. The capacity of a 16-cell battery is 115 ampere-hours, making for the two a total of 230 ampere-hours, and at an average pressure of 1·9 volts for the cells, 6,992 watt-hours are obtained.

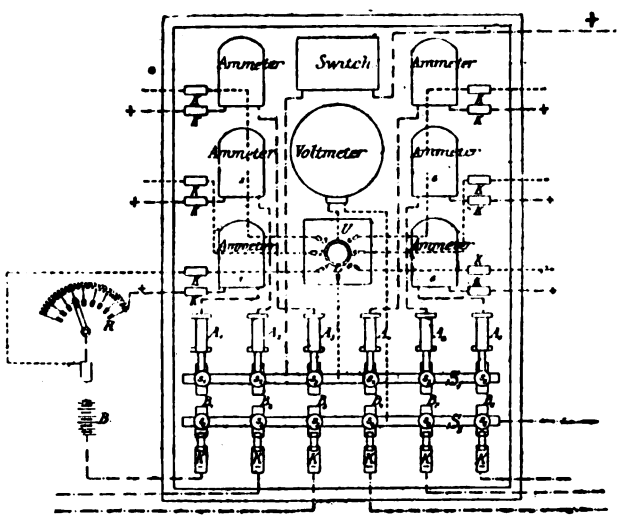
Digitized by Google

Lamps.—Two sorts of lamps have been employed—namely, 12-c.p. Khotinsky lamps for 30 volts and 0·8 ampere, and 10-c.p. lamps of the type made by the Allgemeine Elektricitäts Gesellschaft, for 30 volts and 0·75 ampere. The Post Office has not yet decided which of the two is the better. The jolting of the wagons has a marked effect by causing rupture of the filaments. So far it has been found that after 10 lamps have been in use a total of 250 hours, one is found faulty. Nine incandescent lamps have taken the place of nine gas lamps in a 40ft. tender. There is much increased convenience, as the lamps can be placed in better position for the sorters. Each lamp can be switched on and off independently, and there is a switch to control the nine simultaneously.

Conductors and Safety Appliances.—The leads offer no difficulties. Wire, with good insulating material, is employed. The wire is carried free in such parts where it will not be injured, and elsewhere is covered with wood. The safety appliances consist of a lead safety fuse for each lamp, which cuts it out as soon as the current reaches four amperes, and a double-pole lead safety fuse for 15 amperes for a whole installation.

Consumption of Energy.—The duration of the lighting depends upon the length of the journey. For instance, between Berlin and Frankfort and Berlin and Eydtkuhnen the return trip takes from 24 to 27 hours. According to the length of the journey, two batteries connected together are employed, or one battery with reserve batteries which are switched on during the return journey, or only one battery. The figures given as to the capacity of the accumulators and the consumption of energy of the lamps show that the batteries will suffice for the longest journeys.

Charging.—At first the accumulators were charged at the head telegraph office in Berlin, but a special charging station has now been established at the Anhalt railway station. Current is taken from the mains. At present two charging circuits are in use. In each circuit two batteries, each of 16 cells and connected in series, can be charged, so that about 85 volts are required as the necessary charging pressure. The strength of the charging current is five amperes, and the charging of two batteries will accordingly take place within 24 hours. The



annexed illustration shows a larger installation with six charging circuits. The positive charging conductor is connected to a switch, while the negative lead is connected with the cross-rail, S_2. Attachments from this cross-bar are connected with the negative poles of the 32 cells. In the diagram the connection for a single battery is shown. From the switch the positive conductor of the charging circuit leads to the cross-bar, S_1, through an ampere-meter, and from there to a rheostat, R. Each circuit thus has its own ammeter and rheostat, R. From the second terminal or rheostat, a conductor leads to the positive pole of the battery to be charged. For the whole charging circuits there is provided a common voltmeter, besides a multiple switch, U, so that, as shown in the diagram, each battery is connected in the simplest manner with an ammeter. The batteries (which consists of eight boxes, each of four cells) to be switched in on each charging circuit are pushed in suitable stands, and connected with the charging bars. This method offers few difficulties, and can be quickly learned by an under official.

The object of the experiments has been attained by the provision of a steady, healthier, and more convenient illuminant for the sorters on the tenders, which will lighten their labours and improve the service. Cheapness was not an object of the authorities, but the experiments have already shown that under favourable circumstances electric lighting may prove cheaper than the gas-lighting.

REGULATIONS FOR ELECTRIC SUPPLY—ROUEN MUNICIPAL COUNCIL.

A schedule of conditions and rules for the installation of public electric supply systems has just been issued by the Municipal Council of Rouen, and we abstract from *L'Electricien* some of the principal regulations under which "undertakers"—to use a well known expression—may be able to supply current from central stations for any and every possible purpose in that town.

No authority or concession will be granted except to French subjects or to French companies with a registered office in the town; the Compagnie Europeenne du Gaz is, however, specially mentioned as exempt from this condition.

Any person or company obtaining a concession must be represented in the town by French subjects having full powers to deal with any question involved, and must undertake, on equal conditions, to give the preference to local manufacturers for all requirements necessary when carrying out and operating any concession.

For overhead wires the concessionary must obtain all needful authority from the Imperial Government, and carry into effect any conditions laid down by the telegraph service. He must also obtain all wayleaves, and cannot use any public building as a support for aerial cables without special written authority from the municipal government. Moreover, he must indemnify the latter from any claims which might be brought against him in consequence of this concession. Branch mains in each case are to be provided, erected—as far as the electricity meter—and maintained by the undertaker at the consumer's expense. The former alone will keep a key to the switches provided by him on the branches to consumer's premises.

Underground mains will not be permitted in subways or sewers. They are, as far as possible, to be placed under the footpaths, in earthenware, masonry, or metal conduits. Their position, depth, and outside diameter will be decided by the Council's engineers in each case. Mains can only be taken under the roadways in order to cross them, and their depth must then be not less than one metre from the surface. Branch mains must not be taken across roadways. Manholes are to be provided at suitable distances for inspecting and testing the network. Their position and arrangement must also be decided by the municipal engineers. All covers are to be provided on their inner face with a layer of suitable insulating material. The cost of moving or displacing any gas or water pipes, etc., must be borne by the undertaker.

Mains are not to be laid at a less distance than one metre from the front of buildings, and the Council must be satisfied that the position adopted will ensure perfect safety to passers-by, as well as freedom of operation to the various public services making use of the streets. This minimum distance may, however, be reduced in the case of streets where the width of footpaths is confessedly insufficient to maintain its being always kept. Branch cables which enter any building must be carried over the intervening space in conduits joined to those containing the street mains.

Transformers, where used, must have cut-outs or fuses on both circuits; and only those which supply an entire street or area with current may be placed under the street-level in masonry vaults having proper manholes and facilities for inspection, and being thoroughly insulated.

Before commencing operations, the concessionary is to provide a plan of the whole network proposed, showing the

Digitized by Google

routes followed and the diameters of all cables and wires to be employed; and this plan is to be revised every three months, corrections and additions being duly made. Other plans—as, *e.g.*, of the branch mains, the provisions made for avoiding sewers, gas and water pipes, etc.—must also be provided. Three days' notice prior to commencing work on any part of the network must be given to the highway engineer, as also when (after completion) any work of maintenance or repair becomes necessary; but in case of breakdown, notice need only be given on the same day that excavations are made.

The undertaker is required, after carrying out the work of installation, repairs, etc., to make good, both temporarily and permanently, the surfaces both of roadways and footpaths; otherwise, after due notice, it will be done by the municipal staff and charged to the undertaker. Concessions are to be granted for terms of 20 or 30 years from the date of notifying acceptance, but carrying with them no monopoly or privilege whatever. The Council reserves to itself the absolute right to grant other concessions of the same kind, even within areas affected by networks already authorised. Moreover, it reserves the power to remove, or cause to be removed, any part of established networks whenever the public service may demand it.

Absolute freedom is given to the undertaker so far as tariffs are concerned, excepting only that electric currents are to be supplied by meter, at a maximum of nine centimes per hectowatt—*i.e.*, roughly speaking, 9d. per Board of Trade unit. A supply is, if required, to be furnished for use in the municipal buildings, etc., at not more than half the above maximum rate, and in quantities up to one-tenth of the total output. Similar provisions as regards price of current are enforced with respect to the public street lighting, all material and repairs for which are to be furnished by the undertaker.

In view of possible great improvements upon the present systems of electric lighting, provision is made for holding every five years a conference of four persons—two appointed by the Council and two by the undertaker—for the purpose of examining into the conditions of supply and investigate proposed amendments. A fifth member is to be appointed by the president of the civil tribunal in case of disagreement. Such a commission is to be empowered to make any experiments or trials which may seem necessary. Its expenses are to be borne half by the town and half by the undertaker. It is to hand in a report to the Council within four months after assembling, and consequent upon such report the undertaker may be ordered to carry out the recommended alterations or amendments within a stated time. It is not, however, intended that the expenditure upon these alterations shall be so great as to reduce the net profits below 6 per cent. If the undertaker should refuse to carry them out the Council will take such steps as may seem desirable, to the length of cancelling the concession, but, of course, allowing the undertaker to appeal to the law courts.

Supply of current must, after the concession is granted, be at once afforded within the first zone or area comprised in a circle of one kilometre radius from the central station. Within a year supply must be available throughout the second zone, within a radius of 1½ kilometres; and two years are allowed for supplying the rest of the town, except in the more scattered districts.

The municipal administration is to be allowed full freedom for making the necessary tests at any time, as with the supply of gas. The meters employed are also to be sanctioned and approved by the administration, after careful tests.

The undertaker is to pay to the town as wayleave rental one-fifth of the amount of his gross receipts based on the maximum tariff herein scheduled: having already deposited as caution-money the sum of 10,000f. The concession is liable to forfeiture on the occurrence of any out of the following conditons: transferring powers to a third party; delay in supplying current over the areas conceded; suspension—part or whole—of supply without authority from the Council; non-compliance with the regulations herein laid down, etc.

The Council reserves the right of taking over the entire system at any time after the expiration of 10 years from the date of concession, upon the following terms: an annual sum, based upon the profits of the preceding three years, will be paid to the undertaker for the remainder of the term of concession unexpired, and such payment may at any time be compounded at 20 years' purchase; all plant and machinery—fixed or loose—buildings, etc., will be taken over at a valuation price fixed by experts.

At the expiry of the concession—if the undertaking has not previously been taken over by the municipality, and if an extension of the grant is not sought—the entire system shall become the absolute property of the town without any payments being made. If the concession is not extended, and the municipal administration refuses to accept the undertaking, the concessionary is to take up the network of mains, etc., and restore things generally to their former condition at his own expense.

All responsibility of damage is to be assumed by the undertaker, but injury to the network, accidentally done by contractors employed on work for the municipality, will be made good by the latter. Neglect to carry out these clauses in all their particulars will entail a fine of 20f. in each case per day until remedied. Specific fines are the following: 1f. per street lamp per 15 minutes of extinction during the hours of lighting; 1f. per day for each defect in maintenance or repair; and 10f. per day for each defective appliance not replaced within a stated time. These fines are deducted from the caution-money, which must be made up again within a week. If this is not done, the administration has the right to seize the plant and materials of the undertaker pending satisfaction.

Foreign workmen or assistants are not allowed to be employed in excess of one-tenth of the total staff, and lists of the latter must be submitted to the administration for approval.

SOME NOTES ON THE ELECTRIC LIGHTING OF THE CITY OF LONDON.*

BY MAJOR-GENERAL WEBBER, R.E., C.B.

(Concluded from page 269.)

PUBLIC LIGHTING—LAMPS.

The lamp-posts and lanterns first erected in 1891 by the contractors, to the number of 72, in some of the main thoroughfares, under the pioneer contracts, did not meet with the approval of the Commissioners, and had all in time to be replaced. The only portion which was allowed to remain was the lantern which had been designed by the Brush Company, and which I have illustrated, and called the "Raworth" lantern. My own views had advocated a different shape, having a wide pagoda roof, and sides

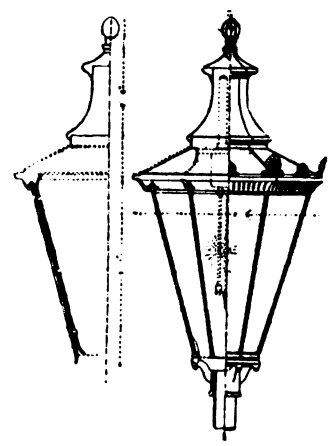


FIG. 22.—Street Lantern.

at smaller angle to the horizontal. In the case of the Raworth lantern, which is in use throughout the City, the dimensions were found to accommodate the Thomson-Houston arc lamp, as well as that of the Brush; the interior is easily accessible, and the lamp, instead of being suspended, stands on a porcelain insulator. The other details are shown on the drawing, and a sample is exhibited. As regards glass, Colonel Haywood was very particular in selecting one that was least absorbent of light, while being sufficiently diffusive of the arc. The first sample, put in by the Brush Company, which gave the effect of there being four small blurs of light inside, was rejected as being too absorbing, and perhaps requiring too much labour in cleaning. Three samples of glass were submitted to the engineer (see those in the lantern exhibited), and

* Paper read before the Institution of Electrical Engineers.

Digitized by Google

tested by him in three street lanterns in use. They were respectively :

	Thickness. Inch.	Per cent. loss by absorption.
Ground glass	0·058	46·24
Opal	0·072	25·18
Rippled	0·145	21·73*

* These tests were, I understand, made by Mr. Preece.

The last was approved, and is now in use, and is the cheapest.

The lamp-posts, as finally designed and approved by Colonel Haywood, are in two pieces, the base having two forms; the smaller base, which is round, is fixed in the narrower footways. As regards the shaft, one matter which required careful consideration was the means of assisting the lamp-trimmer to ascend and descend. In any case, fixed projections below the lantern upon which the man can stand at his work are necessary. These are the arms shown in the elevation. Fixed projections, or means of attaching them, were not admissible on the ornamental base, but something had to be done to assist the man to mount the shaft, so as to save the carrying and use of a long ladder in the streets. The permanent attachment of steps, for obvious reasons, the Commissioners would not allow.

Three methods were proposed—namely : (1) By the Brush Company, in which short pieces of rod iron, with a round head at each end, were passed into holes in the hollow shaft at intervals on alternate sides. These rods lay concealed all except the heads when not wanted ; when in use, they were pulled out as far as the

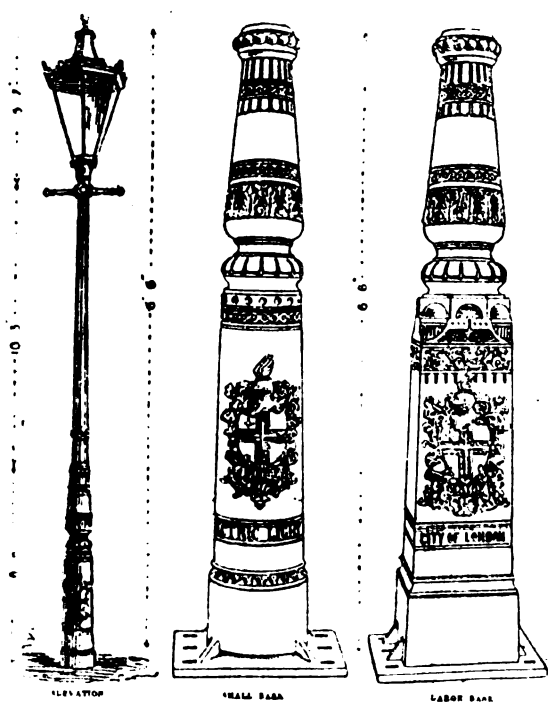

FIG. 23.—Lamp-posts.

head on the rod within the shaft would allow. (2) By Colonel Haywood, which consisted in a structure like a parallel ruler, concealed in and bedded in each side of the shaft. When shut up, no evidence of its existence could be seen ; when opened, the whole has the appearance of a ladder with a centre stave, and, but for extreme complication and costliness, it might have been a very excellent design. (3) The plan which suggested itself to me was very simple, and has been adopted. It consists in using alternate side holes in the shaft, which are not conspicuous, and in having six or eight portable steps of light steel, which can be securely hooked into the holes as he ascends, and taken out by the trimmer as he comes down the post.

Where the footways are very narrow, and posts are inadmissible, it became necessary to use wall brackets. Of one of these, illustrations in two aspects are given. The suspended lantern is the same in design as that on the posts, with some small differences in detail. It took a considerable time for the Commissioners to obtain the way-leaves for such heavy attachments to private buildings. The suspension gear was specially designed to allow the lamps to be independently and rigidly suspended inside the lantern, while the lantern itself is free to swing slightly and swivel round. In both cases—namely, in the base of the lamp-posts, and in a box fixed to the wall under the bracket—an absolute cut-out switch on an incombustible insulating base, approved by the Board of Trade, is provided. Each contractor has his own form.

In connection with fixing the posts, more difficulty than might be expected was found. The base-plates below the ground could not be by any means uniform in pattern. It was impossible to tell before the ground was opened whether the posts could be solidly supported by a deeply-set base, or by one that spread out under the ground. In erecting the posts extra expense was incurred through having to open the ground a second time after the trench for the mains had been made. The Commissioners were responsible for this, owing to delays in approving of the patterns, and in finally deciding on the actual points to place each post. Several forms of modification of these conditions had to be provided for. In some cases heavy masonry and concrete had to be cut through and replaced. Of the 371 arc lamps contracted for in the eastern and central districts, in March, 1892, the positions of 340 only had been decided on. Of the 340 points 37 were brackets. The weights and costs of these posts, above-the-ground brackets, and lanterns are as follows :

A large base weighs 9cwt., 2qr., and costs	£6	0	0
A small base weighs 6cwt., 3qr., and costs	4	10	0
Each shaft and lantern gallery weighs 3cwt., 1qr., and costs	1	18	0
Each lantern weighs 3qr., and costs	7	0	0
Each bracket weighs about 1cwt , and costs	2	2	0

The contracts with the Commissioners provide for the substitution at 906 points of incandescent lamps of not less than 200 watts* for gas lights throughout the City where arc lights have not been put up. It may here be stated that as early as 1888 every point in the City where arc or incandescent lamps would be likely to be required had been surveyed and plotted under my superintendence. The deviation from that design has been very small.

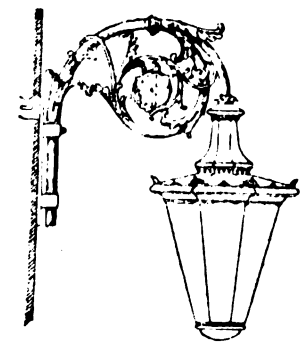

FIG. 24.—Side View, Lantern and Bracket.

The contracts with the two manufacturing companies specified that they are to supply and erect 100 and 200 watt series incandescent lamps ; all arrangements in connection with the first installation to be experimental. The carrying out of these arrangements are still in the experimental stage. The Commissioners had the power to compel the company to complete them in the eastern and central districts by May last ; but in withholding their engineer's order to have this done they have, I think, acted wisely in the interests of public lighting by incandescent lamps.

FIG. 25.—Lantern and Bracket, perspective, and Pipe under, etc.

At the beginning of this paper I stated that the experiment on the Holborn-viaduct in 1882 had brought discredit on this means of public street-lighting. The experiment now going on by the City Company in Basinghall-street is, I think, only calculated to produce the same result ; but it is to be hoped that the Commissioners will be as well advised in this matter as in the past. The principles detailed by Mr. Trotter in his admirable paper before the Institute of Civil Engineers on public lighting by electricity are equally applicable in the case of incandescent lamps as in that of arcs. His dioptric lantern, which we have known ever since

* The prices to be paid by the City for incandescent lamp lighting is (sunset to sunrise)—for a lamp of 200 watts, £10 per annum ; for 100 watts, £5 per annum.

Digitized by Google

the days of the Inventions Exhibition, is the mathematical example of that for which he contends. It is many years since, at the Society of Arts, in a paper on incandescent lamps, I demonstrated that the exposure of the filament to the eye, or the eye to the filament, is an abomination. I do not attempt to supplant Mr. Trotter's originality by showing a sketch of a street lantern with a hood, and inverted truncated glass cone underneath, the glass being cut up throughout a zone of its surface into diamond-pattern facets. There is nothing geometrical in their form (though there might be). They are only intended to intercept the direct view of the filament, within an

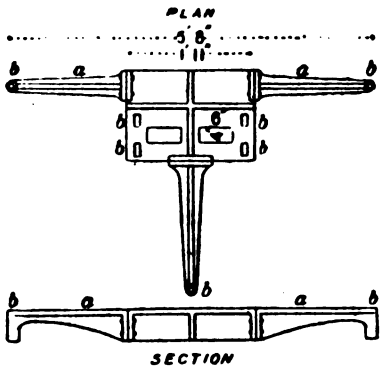

FIG. 26.—Underground Base of Lamp-post.

area of space outside the lantern, and diffuse the rays of light from it. The simplicity of the design as regards convenience, etc., will, I hope, commend itself to the Commissioners; and I believe that if posts in the small thoroughfares and courts were made entirely to disappear, and light ornamental brackets, with lanterns, such as I have illustrated, were used, the City would in this respect have also taken the lead and have set a good example to all other municipal bodies.

This paper, as it title shows, only deals with a portion of the great work of lighting the City of London. Necessarily, my duties as engineer up to July, 1892, required my superintendence of the starting of many works at present far from completion; and while in every case I have been careful to avoid enlarging on matters which could be better described by the engineers more directly responsible, obviously there are also several matters which might be regarded as more or less confidential. These I have

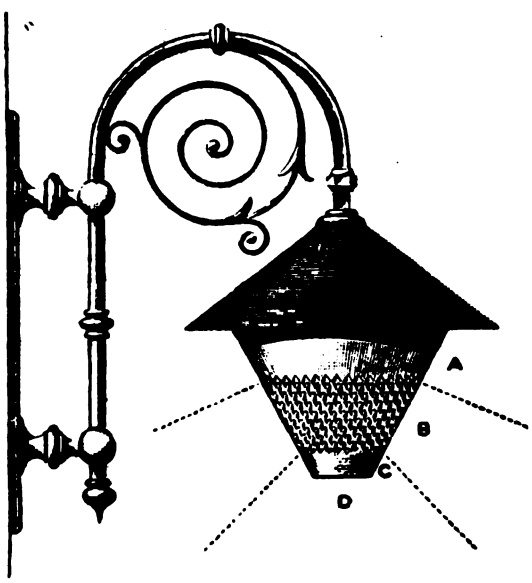

FIG. 27.—Wall Bracket, Incandescent Lamp Lantern.

avoided, and in selecting illustrations from figures have confined myself to those previously accessible to the profession. In concluding, I hope I may be allowed to state that never was an engineer better served than I was by my staff, and that each and all fully justified their selection, equally those who were new to me and those who were old friends. It is no flattery to them to believe that my severance from the position of being their chief has in no way lessened the value of the services which they have since rendered to the shareholders of the City of London Electric Light Company.

DISCUSSION.

Mr. Tasker, who opened the discussion, said that they were all indebted to the author for bringing the points together from a new aspect altogether. It was wonderful that the immense amount of work done had been accomplished in such a short time, and all those who knew anything about the laying of electric light mains would appreciate the difficulties met with in the City.

Mr. G. Kapp remarked that he hardly felt competent to discuss the paper at such short notice because it contained a large amount of difficult matter. He had hoped that the reading of the paper would have lasted until half-past nine, so that they would have had a fortnight to consider the matter and then discuss it. The author had, however, cut out a lot, and had precipitated the discussion. He had also given a large amount of information as to the way he had designed the distributing plant, but he (the speaker) would like to know something about the working of the distributing plant. For instance, one of the illustrations, representing a transformer station, showed the transformers arranged in a two-storeyed building sunk in the ground. The transformers were lowest. He would like to ask what would happen in case water got in. The switchboards were high, but it was doubtful whether they could rely upon the tightness of the casing. Had a method been found of preventing that danger? Another point concerned the various systems of mains used. With regard to the sheathed cables, it was extremely difficult to screen magnetic action, especially if the steel was as thin as No. 22 gauge. The screen would soon be eaten away and the screening effect would be lost. Another point was the question of incandescent lighting in the streets. The author seemed to rather cast a doubt upon the practicability of lighting streets by incandescent lamps. It seemed, however, to the speaker, after all, that incandescent lamps were the right kind of lamps for small streets. When they considered that arc lamps cost at least £25 per annum to keep up, and that a good many arc lamps were required to light a mile of streets, it was an enormous expense, and the expense could only be borne in such parts of the City where the traffic was very heavy, but in all other parts the expense of arc lighting was out of all proportion to the advantages. What they wanted was not a very strong light, but one generally distributed in the streets, and he thought that the incandescent lamp was the right lamp. Moreover, the expense of lamp-trimmers was avoided, and that was a very serious item when many lamps had to be looked after.

Mr. W. B. Esson was of opinion that the paper was more statistical than technical. Like Mr. Kapp, he would like to hear something about the endurance of the distributing work, and also about the watching of sub-stations. There was little given of the actual working of the City lighting.

Mr. Alex. Siemens said that there were some statements in the specification which appeared to him to be entirely against the accepted facts of their profession. The author had told them that the consumption of coal per kilowatt with continuous current was 7lb., and that it did not exceed 5lb. with alternating current. Now that was directly contrary to the results that had been obtained with the use of continuous currents, which could be produced at a cheaper rate than alternating current. It would be interesting to hear some remarks on that point. With regard to telephone wires being protected from interference by the use of iron sheathing, according to the speaker's mind, twin telephone cables (metallic circuits) did not need any protection—they protected themselves against induction. It was almost invidious for him to say a word in favour of lead-cased cables, and he was only doing so because the other lead cable makers seemed to be absent. With regard to the conduits, he thought he would prefer laying lead-covered cables which could be threaded about, under and over gas-pipes and other obstructions without any difficulty. Then again, very great precautions against explosions of gas had not to be taken, because the gas could not get there.

Mr. Braithwaite, in the course of a few remarks, took exception to certain references made by the author in regard to preliminary expenses in connection with the City company.

Mr. J. F. Albright endorsed the remarks made by Mr. Braithwaite. He had had experience in trying to get carried out schemes of that kind, but if preliminary expenses were to be avoided the projects could not be dealt with. He thought there should be no question among engineers that a certain amount of that kind of financing was justifiable. The author of the paper appeared to be rather hard on the incandescent lamp for public street-lighting. When the incandescent lamp was well used, it was undoubtedly a suitable lamp for street illumination. He did not agree with the policy of adopting the Callender-Webber cable system to such a large extent. He believed the best system before them was that of wrought-iron pipes with first-rate insulated cables drawn in.

Prof. Silvanus P. Thompson stated that the abstracts which the author had given of his views did not contain the whole of his views. He did not wish to impute any unfairness in the matter, but as the reports referred to were not his property he was naturally debarred from referring to them. There were certain opinions of his quoted, and which might be fallacious. He might report that the correct thing for electric lighting was vertical engines with direct current. Well, his opinion on that point might be worth nothing. He gave that opinion for a particular station and for a particular district. His view given for a particular district might not apply to another district, when a convenient site could be had for nothing. He was not at liberty to reply to the opinions he had given concerning the use of incandescent lamps for street-lighting. It appeared to him that it was largely a question of the way in which the lamps were used. He wished they could point to more experience of series lamps in incandescent lighting. There were many cases in large, and particularly in small towns, where arc lighting was not the right thing, and where every arc gave far more light than was wanted. A larger number of smaller lamps would be obviously the right thing. With respect to the use of dioptric shades, they all know how the City Company had carried out the attempt to diffuse the light by means of such shades. That was a subject which might claim a special discussion itself. One thing could be done in this way by the use of proper shades—namely, abolish for ever the dark shadows under the arc lamp.

Mr. R. E. Crompton said that the author had given them the cost of a high-pressure feeder 1,200 yards long at £5,146, and that the annual charge might be put down at £367. He had also contrasted that with the cost of a low-pressure feeder which he made out to be £15,660, and he had challenged him on the matter. Well, he (the speaker) had run the cost out, and made it about £4,400. That was not a mere statement—he was prepared to execute work at that figure. But when he came to maintenance the figures were more interesting. The author had mentioned £161 for paying capital in 21 years at 4 per cent., upkeep and depreciation £136, attendance and small stores £70, or a total of £367. Mr. Crompton, however, from his large experience in the maintenance of mains, knew the expense, and he asserted that there was no trouble in keeping such a feeder in order for £20 a year; the interest and sinking fund would be £130, so that the total cost would be £150, as against £367 mentioned by the author. Was the latter right, and the speaker wrong? He thought in a few years' time nothing but experience would guide them, and the accounts of the company in a few years would show which was correct. Up to the present, however, the accounts of the low-pressure companies showed that it was the lowest and very well maintained. The paper could not be discussed on its merits at such short notice.

Major-General Webber then replied to the discussion. It was true, as Mr. Kapp had pointed out, that the discussion had been precipitated by his having curtailed the paper, but when he had put his thoughts on paper, he found there was more than could be dealt with in the time available. He condensed the paper in reading in accordance with a promise made to the chairman that it should not occupy more than an hour. The question of the screening effect had largely occupied his attention. He believed that the only reason a sound was heard during the experiments referred to, was because the wires were parallel instead of being spirally twisted. It was, of course, necessary to prevent any possibility of disturbing telephone wires in the event of their being laid parallel, and he did not think that they could say that the money spent had been thrown away. Mr. Esson had referred to points against which he (the author) in the paper had guarded himself; the experience of working could only come from those who had had that experience. The paper he had presented chiefly described work the working results of which had been obtained, at the same time confining himself to work designed or superintended by himself. Mr. Siemens remarks about 7lb. and 5lb. were probably due to his not having read the paper with sufficient care. The 7lb. was allowed as a well-known figure, which could not be departed from when it was settled beforehand that the arc lamps were to be run by Brush and Thomson-Houston dynamos, and if any other figures had been put the contractors would not have been prepared to accept it. The 5lb. for an alternating plant was very good, and one which there was every prospect of being able to keep to with regard to the cables adopted, as against lead-covered cables. It was much better to have conduits into which they could draw in fresh cables when necessary, than to be compelled to do as the gas companies did years ago—namely, lay down small pipes and be compelled to replace them by larger pipes. Concerning Prof. Thompson's statements, he (the speaker) did not wish to quote him literally, but at the same time it was natural, with his experience, that he should point to his statements in justification for proceeding with a great work like that. He was glad to hear from Mr. Crompton that his figures had brought out from him a statement of enormous value, but there was one point which he did not answer — namely, whether the £4,400 would construct a conduit which would be found within the sectional area he had given. [**Mr. Crompton** here replied in the affirmative.] The author was only too glad that his paper had been the means of calling forth such a difference in figures.

The **Chairman** then called upon the meeting to propose to the author for his paper a vote of thanks, which was unanimously passed.

LEGAL INTELLIGENCE.

MUIRHEAD AND ANOTHER v. THE COMMERCIAL CABLE COMPANY.

In the Queen's Bench Division of the High Court of Justice, on Wednesday, before Mr. Justice Kennedy without a jury, this action was heard. The plaintiffs, John and Alexander Muirhead and Herbert Arnand Taylor, the patentees and proprietors of certain patents for the system of duplicating cables, known as the Muirhead Duplex System, sued the defendants, a foreign company, incorporated under the United States laws, the owners of certain cables connecting North America and Ireland and Ireland and France, to recover royalties under a written agreement, dated January 2, 1884, giving the defendants a license to use certain patents of the plaintiffs in consideration of a yearly payment of £1,250, to be increased in certain eventualities. The sums claimed were £1,879. 18s. 9d. for royalties from July to September, 1891, and £1,685. 2s. 8d. for royalties from September to December, 1891, making in all a sum of £3,566 odd. The defendants admitted the deed of contract and also a *primâ facie* liability under it; but they alleged that the patents in question had run out at a certain date, and they paid all the royalties due from them up to that date into Court. Thus the defendants undertook the onus of proving that the plaintiffs' American patent of 1880 terminated at the same date as their English patent, by the law in the United States that enacts that "every patent granted for an invention which has been previously patented in a foreign country shall be so limited as to expire at the same time with the foreign patent." In order to establish that contention, it was necessary in effect to show that the plaintiffs' American patent of 1880 was substantially identical to their patent of 1876. The plaintiffs pleaded that such a course was not open to the defendants on the doctrine that a licensee cannot attack the validity of the patent for which the license is granted any more than could a lessee attack his landlord's title though he could show that the lease had expired.

Mr. Finlay, Q.C., Mr. Bousfield, and Mr. E. H. Pollard appeared for the plaintiffs; and Sir Richard Webster, Q.C., Mr. F. S. Moulton, Q.C., and Mr. A. J. Walter were for the defendant company, and Mr. Carpmael held a watching brief for an interested third party.

At the conclusion of the arguments Mr. Justice Kennedy reserved his judgment.

COMPANIES' MEETINGS.

CITY OF BATH ELECTRIC LIGHTING AND ENGINEERING COMPANY, LIMITED.

Directors: T. O. Callender, London, chairman; Alfred Pitman, Bath; B H. Van Tromp, London; C. J. Wharton, London; J. B. Wood, London; Ernest Pitman, Bath. Secretary: Wm. Jeffery, 2, Northumberland-buildings, Bath. Engineer and manager: G. F. Metzger, A.I.E.E.

Report of the directors presented at the third annual general meeting of the Company, held at the works of the Company, Dorchester-street, Bath, on Wednesday, March 7, 1894.

In submitting the balance-sheet and profit and loss account for the year ending December 31, 1893, the directors are pleased to be able to state that the year's working shows a substantial improvement over 1892. The receipts for the current sold are increasing satisfactorily, the total income from this source being £4,621 as compared with £4,301 for 1892. The number of lamps installed has risen from 6,420 to 7,070, and the directors anticipate considerable additions during 1894. The policy of charging by meter only has been steadily pursued—a plan alike fair to the consumer and the Company. The directors have appointed Mr. G. F. Metzger as engineer and manager, and he commenced his duties in May. With his help considerable economies and improvements have been effected, whilst the efficiency of the station and the plant has been fully maintained. These economies have resulted in a profit for the past six months of £464, notwithstanding the additional expenditure involved by the coal strike. Had it not been for a loss on the first six months of £276, and the loss of £277 brought forward from last year, the profit for the year would have been satisfactory. As it is not anticipated that similar losses will again occur, the directors look forward with every confidence to 1894. It may be satisfactory to the shareholders to be informed that the existing machinery and plant are capable of a largely increased output of current without materially increasing the running expenses. The financial position of the Company has also been considerably improved since the last report, and since the closing of the year's accounts the unpaid balance of purchase-money, amounting to £1,242, has been paid. Since the last meeting Mr. E. Garcke, Major-General J. G. Jervois, Mr. H. N. Garrett, and Mr. H. G. Massingham have retired, and the directors have elected Mr. B. H. Van Tromp and Mr. J. B. Wood to the Board. The following directors retire and offer themseles for re-election: Mr. Alfred Pitman, Mr. Ernest Pitman, and Mr. J. B. Wood. The directors waive their fees for the past year.

The annual meeting was held on Wednesday at the offices in Dorchester-street, Mr. T. O. Callender, chairman of the Company, presiding.

The **Chairman**, in moving the adoption of the report and accounts, said the directors were sorry they could not recommend the declaration of a dividend. They would see from the accounts that the directors had divided them into two half-yearly statements, so that the shareholders could see for themselves the progress of the Company, especially during the latter part of the year. They were not very fortunate during the first half, but in the latter six months their business was, to say the least, fairly satisfactory, and they believed the arrangement that had been made would enable them to conduct their subsequent business on the same lines. They hoped their success would be even greater, and all the Company needed was an extension of the number of customers. He felt it should be a satisfaction to the shareholders to know that the Company's plant was capable of supplying a very much larger number of lamps, that their mains ran past the doors of most houses in the city, that they had laid out the network thoroughly and completely, and that all they now wanted was a larger number of citizens to adopt the illuminant. The directors had found that the old contract system did not work out satisfactory, and the meter system which had been subetituted was considered on all hands to be the fairest and best. Alluding to the accounts, he pointed out that while the revenue of the Company had considerably increased, their expenses remained practically the same. Many alterations had been carried out at the works; Mr. Metzger had been appointed engineer and manager, and the directors were glad to say that with his assistance considerable economies and improvements had been effected. The machinery and plant had also been thoroughly improved, and the station was now in a much better condition than it had ever been. There had been several changes in the board of directors, several having retired, while Mr. B. H. Van Tromp and Mr. J. B. Wood had been elected.

Mr. Van Tromp seconded the motion, which was unanimously carried.

Mr. E. B. Titley moved the re-election of the retiring directors, and the motion was carried. Mr. Butcher was then reappointed auditor, and the meeting terminated.

SCARBOROUGH ELECTRIC SUPPLY COMPANY, LIMITED.

The second ordinary general meeting of the shareholders of this Company was held last week at the offices of the Company, 102, Westborough, Lieutenant-Colonel Steble in the chair.

The **Chairman**, in moving the adoption of the report and balance-sheet, which were given in our issue of the 23rd ult., said that last year at this time the Company had not a brick laid. Now their supply station was in full working order, and two dynamos capable of energising 5,000 lamps were in operation. They had accommodation for five more engines and one boiler when they required them, and therefore they were fully prepared to make the additional supplies of electric light which they might fairly anticipate in the near future. He congratulated the Company on the success it had so far attained, and said that the favour in which the illuminant the Company supplied was held was still spreading. The Company's capital expenditure had been about £20,000. That, he thought, was very small, considering that it included the cost of mains and cables. They had now, he mentioned, 5½ miles of mains, and nearly 18 miles of cables laid. He hoped that before very long they would require more machinery, and if that were so they would require more capital. It would be for the directors to consider how it should be raised, and it might be that they were to issue a certain number of debenture to cover the cost of additional machinery, mains, and cables. He was looking forward with some confidence to the day when electricity would not only benefit Scarborough and the Company materially, but also benefit the health of the borough. In saying that he was thinking of the experiments which were now being made in utilising town refuse for the generation of electricity instead of coal, and anticipated a favourable result. If the experiments should succeed, and the Company could generate electricity in that way, the Company would of course be able to supply the light at a much cheaper price than they were doing now. Already, however, the Company were not charging consumers the prices they were entitled to and which they charged during the first five weeks of the Company's existence. They were now charging from 5¾d. to 6½d. per unit, less 5 per cent. discount on accounts settled within a reasonable time, and that was most reasonable compared with the prices of many other companies.

Mr. A. A. Campbell Swinton, who seconded the motion, said that the question of dividend was the one that probably interested the shareholders most. The receipts amounted now to £125 per month, and just about balanced the expenditure. With the addition of 2,000 or 3,000 more lamps, therefore, the Company would be in a fair way to paying a dividend. It was difficult, however, until they had been working one year to make accurate calculations. The machinery at the Company's generating station had been working satisfactorily. They had had less difficulties than many other companies, and they had got over them more quickly. The amount expended on capital almost exactly corresponded with the original estimates, the only difference being that they had laid rather longer mains than they planned.

The motion was then put to the meeting and adopted.

Mr. G. L. Beeforth, the Hon. C. A. Parsons, and Mr. G. Alderson-Smith were re-elected directors, and Mr. C. E. Bradley was reappointed auditor.

YORKSHIRE HOUSE-TO-HOUSE ELECTRICITY COMPANY, LIMITED.

The ordinary general meeting of the shareholders in this Company was held on Tuesday at the central electric lighting station, Leeds, Mr. Grosvenor Talbot, chairman, presiding.

The **Chairman**, in moving the adoption of the report and balance-sheet (which were given in our last issue), said that since the meeting in May last the directors had not only had a busy and laborious time, but also a time of considerable anxiety. Fortunately they were able to show a profit for the eight months of £1,155, and that, he believed, was very different from what most electric lighting companies had been able to show under similar conditions. The result was all the more satisfactory in that the period covered was the worst of the year so far as the use of electric lighting was concerned. The directors had thought it better to at once reduce the sum expended on preliminary expenses, and had applied £1,000 of the profits to the £2,185 disbursed in those expenses. A similar sum would not be put aside another year, because allowance would have to be made for depreciation, which had not been done this year because the plant of the Company was all new. The Company had encountered two difficulties during the year, one being the unusually bright winter and autumn, and the other the coal strike. Still, they had found it necessary to increase the capacity of their works in order to keep pace with the demand for electric lighting on the part of their customers. In Leeds there was a larger proportion of lamps burning at one time as compared with the number of lamps installed than in almost any other district. The directors had found it absolutely necessary to make provision for an increased demand next winter, and were enlarging the capacity of the engines from 1,100 h.p. to 1,800 h.p. They had made the Corporation an offer to supply the City Hall and Municipal Buildings with electric light at a price which they believed to be considerably within the cost now incurred by the Corporation according to the latter's published accounts. They had also decided to reduce the price of the light per unit 12½ per cent., so as to encourage its use by the general body of consumers, and as the demand increased they would be able to make still further reductions He had the greatest confidence that they would be able to establish a large, thriving, and profitable electric lighting establishment. Electricity was evidently going to be the light of the future, and the only wonder was that the Company should have been allowed to have the opportunity of such a valuable opening as they now possessed of supplying the light to Leeds. He hoped they would avail themselves of that opportunity by doing their best for the citizens.

Mr. Crowther seconded the resolution, which was carried.

Messrs. Crowther and A. G. Lupton were re-elected directors, and Mr. John Gordon, jun., was reappointed auditor.

COMPANIES' REPORTS.

HOVE ELECTRIC LIGHTING COMPANY, LIMITED.

Directors: Colonel A. J. Filgate, R.E. (chairman); Colonel H. Wood, C.B. (vice-chairman); Harold A. Hoare, Esq.; Carleton F. Tufnell, Esq.; John Wilkes, Esq. Engineers: Messrs. Crompton and Co., Limited. Secretary: Francis R. Reeves, Esq.

Report of the directors to be presented at the annual general meeting of the shareholders at the Town Hall, Hove, on Wednesday, March 14, 1894.

The directors beg to submit to the shareholders the statement of accounts and balance-sheet made up to December 31, 1893, in the form prescribed by the Board of Trade. The statement herewith covers the whole period since the formation of the Company in August, 1892, and is intended to supersede the interim statement submitted to the members on December 12 last. The directors have pleasure in again congratulating the shareholders on the progress of the Company. The number of lamps attached to the Company's main is now equal to 6,915 8-cp. lamps, and the number of houses has increased to 105. From the accompanying statement of accounts it will be seen that the working of the Company has resulted in a small profit at December 31 last, and from the increasing number of new customers and additional lamps connected each week, the directors look forward with confidence to a very satisfactory profit at the end of the current year. The opposition company, the Brighton and Hove Electric Lighting Company, who are supplying a certain number of consumers in Hove with electric current from overhead wires, have been directed by the Board of Trade to make certain alterations in their system of conductors, but they have, it is believed, decided to discontinue their operations in Hove altogether, and consequently your directors expect a large accession of lights to their system shortly. Indeed, at the present moment they have applications from consumers with nearly 3,000 additional lights. Since the date of the interim report the directors have allotted 756 additional shares, bringing up the total allotted to 4,046 shares, representing a subscription of £20,230, while the capital expenditure amounts to £29,236, and consequently there are large balances due to the contractors and others, in addition to which the Company's further commitments on capital account amount to nearly £13,000. It is therefore necessary that further subscriptions for capital be obtained, and the directors would urge upon the members to subscribe for the balance of the Company's shares, a prospectus of which accompanies this report. Immediate application is necessary, as the directors intend to offer to the public any shares not applied for by the members on or before the 10th inst. Colonel A. J. Filgate and Colonel H. Wood, C.B., retire from the Board by rotation, and, being eligible, offer themselves for re-election. Mr. Robert Payne, F.C.A., the auditor of the Company, also offers himself for re-election.

BIRMINGHAM ELECTRIC SUPPLY COMPANY, LIMITED.

Directors: Henry Buckley, chairman; Geo. S. Albright; J. F. Albright; G. H. Johnstone; Francis W. V. Mitchell; J. C. Vaudrey, managing director.

Report of the directors submitted to the shareholders at the ordinary general meeting of the Company, held at the offices of the Company, 14, Dale-end, Birmingham, on Thursday, March 8.

Your directors have pleasure in presenting their fourth annual report and balance-sheet. The amount of net profit, including the balance of £264. 1s. 8d. carried forward last year, is £5,247. 16s. 8d.; out of this the directors recommend the payment of a dividend of 4 per cent., absorbing £2,715. 6s. 7d., placing £1,872. 18s. 1d. to the credit of the depreciation reserve fund, and a further sum of £250 towards the general reserve fund, and carrying forward the balance, £409. 12s, to next year's account. The capital expenditure during the year amounts to £5,356. 10s. 9d., and includes the addition of one new steam-engine and dynamo machine, and further extension of the Company's mains and services. The total number of 16-c.p. lamps or their equivalent on order on December 31, 1892, was 8,329, and on the same date in 1893 the number was 10,223. The demand for the light still continues to increase, and the additions since the close of the financial year bring the total up to 11,034. The directors venture to think that the progress made during the year that has passed will not be considered unsatisfactory, taking into consideration the depressed condition of trade, the prolonged coal strike, and the phenomenally clear days throughout the winter months. At the last annual meeting your directors reported that they considered, owing to the demand for the light in some of the outlying districts, that it would be an advantage to the Company to extend its operations to Edgbaston and the jewellers' quarter. The necessary statutory notices have been given, and a draft of the new provisional order for the additional areas is now under discussion with the Corporation. In accordance with the articles of associations, two directors, Mr. Henry Buckley and Mr. J. F. Albright, retire by rotation, and being eligible offer themselves for re-election The auditors, Messrs. Sharp, Parsons, and Co, also retire, and being eligible offer themselves for re-election.

BALANCE-SHEET, DEC. 31, 1893.

BUSINESS NOTES.

Great Northern Telegraph Company.—For the month of February the receipts were £20,000

Hobart Electric Tramway Company.—For the month of February the receipts were £1,431.

Western and Brazilian Telegraph Company.—The receipts for the week ended March 4 were £3,001.

Change of Address.—The address of Mr. Robert Hammond is now Ormonde House, Great Trinity-lane, E.C.

Canterbury.—A meeting of the Town Council will shortly be held to consider the question of electric lighting.

Hartlepool.—The Corporation decided on Tuesday to defer *sine die* the question of introducing the electric light.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 4th inst. amounted to £635.

Cuba Submarine Telegraph Company.—For the month of February the receipts were £165 less than for the corresponding period of 1893.

Eastern Telegraph Company.—The receipts for the month of February were £54,904, as against £55,281 for the corresponding period of 1893.

Eastern Extension Telegraph Company.—For the month of February the receipts show a decrease of £4,346 as compared with the corresponding period of 1893.

Tenders for Lighting Tramcars.—The Glasgow Corporation, as will be seen from our advertisement columns, invite tenders for the electric lighting of 240 tramcars.

West India and Panama Telegraph Company.—The receipts of this Company for the two weeks ended February 28 were £111 less than for the corresponding period of 1893.

Tender Accepted.—The tender of Messrs. S. Dixon and Son, of Boar-lane, Leeds, has been accepted for lighting the Dewsbury workhouse and premises by electricity, for the Guardians.

Crewe.—On Saturday last a fire broke out in the electric accumulator-house at Crewe Works. Considerable damage was done to the buildings, and nearly all the acid-tanks were broken by the heat.

York.—Mr. Arnold Taylor has conducted an enquiry with reference to further borrowing powers sought by the Corporation. The loans include the sum of £350 for the electric lighting of the public library.

Personal.—Mr. H. M. Sayers, now superintending engineer of the Companhia de Luz Electrica, Oporto, has been appointed superintending engineer of the Bournemouth and District Electric Supply Company.

Brazilian Submarine Telegraph Company.—The directors have declared an interim dividend of 3s. per share, or at the rate of 6 per cent. per annum, free of income tax, for the quarter ended December 31 last.

Edinburgh.—The Corporation Electric Lighting Committee have agreed to charge for electricity 6d. per unit for lighting, and 3½d. per unit for motive power. This proposal has been adopted by the Corporation.

Latimer Clark, Muirhead, and Co., Limited.—Mr. Justice Vaughan Williams on Wednesday made an order that the voluntary winding-up of this Company should be continued under the supervision of the Court.

Traction at Newcastle.—The Newcastle City Council on Wednesday, at the request of the Special Tramways Committee, sanctioned the expenditure of £300 in gathering information as to the various systems of traction.

Chelmsford.—At a meeting of the Town Council last week the Lighting Committee presented an estimate for the lighting of the borough for the ensuing 12 months. The total cost would be £995, with £5 additional for lighting the public clock.

The Tenders for Bury.—To-morrow (Saturday) is the last day for sending in tenders required by the Technical School Committee of the Corporation of Bury for the supply of electric light fittings, including switchboards, lamps, wiring, etc., for lighting the technical school.

Halifax.—The Gasworks and Electric Lighting Committee have decided to buy 70 yards of land situate on the west side of the electric lighting station site, from the Vicar of Halifax at 23s. 3d. per yard, and 87 yards of land adjoining from Mr. Alfred Bancroft at 25s. per yard.

Bolton.—Messrs. Dobson and Barlow, Limited, of Bolton, have placed with Messrs. Lowcock, Hill, and Co., of Manchester, the order for the lighting of a portion of their machine-shop with 120 inverted arc lamps, and also a large extension of their incandescent installation with dynamo.

Messrs. J. Stone and Co.—We understand that the well-known firm of Messrs. J. Stone and Co., sanitary and general engineers, of Deptford, S.E., have recently opened an electrical department, and that they are devoting considerable attention to the electric lighting of trains and of steamers.

City of London Company's Debenture Stock.—The applications for the £100,000 5 per cent. debenture stock of the City of London Electric Lighting Company, Limited, which has just been issued, amounted to £1,288,835. The letters of allotment and regret were posted on Wednesday evening.

Tenders for Blackpool.—The trustees of the United Methodist Free Church, Adelaide-street, Blackpool, invite tenders for fitting up the church with electric light. Parties tendering to furnish their own designs. Information respecting same may be obtained from Mr. George Johnson, 16, South Beach, Blackpool

City and South London Railway.—The receipts of the Company for the week ending March 4 were £934, against £929 for the same period last year, or an increase of £5. The total receipts for the first half-year of 1894 show a decrease of £128 compared with those for the corresponding period of 1893.

Oswestry.—It was mentioned at a meeting of the Town Council on Monday that the deputy town clerk and Councillor Spoull had attended on February 17 at the Board of Trade office with regard to the electric lighting of Oswestry, and that the Board were satisfied as to the stability of the electric lighting company.

Proposed Electrical Exhibition at Derby.—Mr. Marsden proposed, at a meeting of the Town Council on Wednesday, that an electric lighting exhibition should be held at Derby, and that the Electric Lighting Committee be empowered to spend £200 on the project. Mr. Leech seconded the motion, which was carried.

Chatham.—At a meeting last week of the Town Council the Mayor gave notice of his intention to move that the local electric light and power company should be asked to state the terms upon which they would be prepared to supply current to electric tramcars upon a route extending from the Luton Arch to Star-hill.

United Asbestos Company, Limited.—The directors of this Company recommend the payment of the following dividends for the past year: 10 per cent. on the £10 preference shares, 6 per cent. on the £5 preference shares, and 2½ per cent. on the ordinary shares, carrying forward a balance equal to 5¾ per cent. on the ordinary shares.

Tenders Wanted for Brighton.—The Town Council of Brighton invite tenders for the supply and laying of armoured and lead-covered electric cables. Specifications can be obtained on application at the office of Mr. Francis J. Tillstone, town clerk, Town Hall, Brighton. Sealed tenders must be left at his office by Monday, March 12.

Tenders Required for Leamington.—The Corporation invite by Monday, the 12th inst., tenders for the erection of five short lines of telephone wires, and for the provision and fitting up of six sets of telephonic apparatus complete in all respects. Plans and specification may be seen at the office of Mr. de Normanville, the Corporation engineer, at the Town Hall.

The Harrogate Tenders.—It may be well to remind intending contractors that next Wednesday is the last day for sending in tenders invited by the Corporation of Harrogate for refuse sorting and drying plant, with accessories, steam-boilers and accessories, steam and exhaust pipes, transformers and accessories, and distribution mains for the proposed central station.

National Telephone Company.—The staff dinner of this Company took place last week at the Holborn Restaurant, under the presidency of Mr. E. L. Gaine (the general manager). There were 200 gentlemen at dinner, including Sir A. K. Rollit, M.P., Mr. A. Anns (the secretary), Mr. Dane Sinclair (engineer-in-chief), Mr. G. H. Robertson, Mr. W. A. Smith, Mr. J. Ardrons, Mr. C. S. Agnew, Mr. R. W. Wallace, etc.

Dover.—The Town Council last week received a letter from the Board of Trade in reference to the representation which had been forwarded them on their electric light regulations, stating that they had given the matter careful consideration when the regulations were drawn up, and that they could not see their way to make any alterations. They also pointed out that overhead wires were not allowed without their express permission.

Glasgow.—At a meeting of the Town Council last week Bailie Primrose called attention to the defective electric lighting in the City Hall. Bailie Pettigrew explained that the committee were satisfied that the system of lighting in the hall was all that could be desired, but the lamps at present in use had been put up only temporarily, and when the new lamps were fitted up the objection which Bailie Primrose urged would be entirely removed.

Maidstone.—It will be remembered, as stated in our issue of 23rd ult., that the question of entrusting Messrs. Bourne and Grant with carrying out the electric lighting order of the Local Board, was adjourned from the last meeting for further consideration. Alderman Ellis last week again formally moved that the committee's report be adopted. Mr. Baker seconded, but after some discussion the matter was again adjourned for a fortnight.

Digitized by Google

The Strand.—The District Board of Works have resolved that the report of the Works Committee on the subject of improving the lighting of the Strand district, at a sum not exceeding the amount mentioned in the surveyor's report presented at the last meeting, be adopted on its further consideration by the committee with certain suggestions made by the proposer of the resolution.

The Tenders for Edinburgh.—Saturday, the 17th inst., is the last day for receiving tenders required by the Corporation of Edinburgh for the following work in connection with electric lighting: construction of concrete culverts and laying of stoneware and iron pipes and casings; supply of cast iron pipes, casings, and road service boxes; supply of stoneware casings and insulators; supply of copper strip; and supply of armoured and unarmoured insulated cable.

Fleetwood.—At a meeting last week of the Improvement Commissioners, Mr. Hudson mentioned that there was a correspondence going on in various journals respecting the merits of certain dynamos worked in parallel in connection with electric lighting stations. It was thought desirable the Board should await the results of the working of these dynamos at certain places, and the Electric Lighting Committee were empowered to visit several places, if required, to inspect.

Burnley.—At a meeting of the Board of Guardians, Mr. Thompson raised a discussion on an expenditure of £45 for providing electric lighting fittings to the union offices, and contended that the resolution passed at the last meeting was out of order, as no notice had been given. The clerk informed him that the resolution was perfectly in order. The question was referred to the Finance Committee for consideration, and they brought forward a recommendation, which the Board adopted.

Grange.—The chairman to the Local Board, having ascertained from the clerk that the cost of obtaining a provisional order would be about £250, which was a much larger sum than he had anticipated, has withdrawn his motion for applying for such an order. At the same time he feels strongly that they should not lose much more time before going into the question of the cost of the lighting of Grange, his own opinion being that some system of electric lighting would be much cheaper and better than the present costly system. He hopes, therefore, the question will not be lost sight of.

Tenders Required for Sutton.—The Sutton (Surrey) Local Board invite tenders for the purchase of their powers granted to them by the Board of Trade under the Sutton (Surrey) Electric Lighting Order, 1892, for the lighting of the district comprised in the provisional order. The system proposed to be adopted is the low-tension system. All further particulars can be obtained of the Board's surveyor, Mr. A. D Greatorex, C.E, and copies of the specification and proposed deed of transfer may be obtained at his office at a charge of £1. 1s. Tenders should be addressed to Mr. Thos. D. Pettiver, clerk, Local Board Offices, Public Hall, Sutton, Surrey, by April 4.

Edinburgh Corporation Electrical Engineer.—The Electric Lighting Committee of the Town Council have selected for decision the following gentlemen to be recommended to the Town Council from the 98 applicants for the post of electrician to the Corporation: Mr. R. A Chattock, Metropolitan Electric Supply Company, Limited, Amberley-road station, London; Mr. George B. Dunn, Metropolitan Electric Supply Company, Sardinia-street station; Mr. E. W. Monkhouse, M.A, Westminster Electric Supply Corporation, Limited, Eccleston-place. On Tuesday the Corporation appointed Mr. Monkhouse resident electrical engineer at a salary of £300 per annum.

Morecambe Electric Light and Power Company.—The third annual meeting was held last week, Mr. C. Mabbott presiding. The report showed an expenditure on revenue account of £1,361 and receipts £1,546, leaving a gross profit of £185. The subscribed capital had advanced from £2,782 in 1892 to £5,640 in 1893 the debenture capital from £1,000 to £1,500, expenditure on plant, cables, etc., from £4,317 to £7,250, gross revenue from £577 to £1,281, number of lamps fixed from 1,200 to 2,400, 832 new shares had been issued since the end of the year, and of the 500 shares for the Sandylands extension 370 had already been taken up. The report was unanimously adopted, and a dividend of 2 per cent. declared.

Messrs. Rashleigh Phipps and Co.—This Company, of 102, Oxford-street, are at present engaged upon the installation of nearly 1,000 additional lights at Messrs. Marshall and Snelgrove's large premises in Oxford-street and their new premises in Vere-street. A complete plant is being established to run these additional lights, large additions to the present engine-room having been effected to accommodate the two engines and dynamos and four sets of accumulators. This firm has also recently completed an installation of some 300 lights for the Hon. H. Sturt, M.P., at his new house, 38, Portman-square, with great success; they are also engaged upon the lighting of some 20 other private houses in various parts of London and district.

An "Electrical" Bazaar.—On Wednesday Lady Randolph Churchill opened an "electrical" bazaar, promoted by the Bradford and District Teachers' Association, in the Technical College, Bradford. The lecture hall of the Technical College is given up for sale purposes, and presents a brilliant spectacle. The windows are darkened, and from the decorated stalls incandescent lights glow by day as well as in the evening. In the centre of the hall is an Eiffel tower, lighted from within by incandescent lamps. The other rooms are similarly treated, while from the cupola of the college at night a 15,000-c.p. search-light serves as an advertisement. The installation has been carried out by the Wray Electric Engineering Company, of Bradford,

Derby.—At a meeting of the governors of the Derbyshire Royal Infirmary, the Building Committee reported that they had had under consideration the necessity for entering into a contract for the provision of electric light for the four large and four small wards now nearly completed. Colonel Buchanan moved the adoption of the report. He stated that the committee would use the electric light for the present on a small scale in those parts of the institution where it was essential that everything detrimental to health, even in the smallest degree, should be excluded. Sir John Smith seconded the adoption of the report, which was carried. It was decided to invite estimates for the work.

Longitudinal Wedge Seam Joint Steel Tubes.—This tube has been patented by Mr. Frank Williams. It is claimed that it can not only be supplied at less cost than riveted steel tubes, but it can also be made to stand pressures up to 800lb. per square inch. The tubes can be shipped in plates ready to be put together at their destination at little cost, and effecting, it is said, a great saving in freight on foreign orders. These tubes can be made in any lengths consistent with the rolling of the plates, and to almost any diameter, with special or ordinary couplings to suit requirements. They are manufactured by Messrs. Frank Williams and Co., Eagle Works, Wolverhampton, whose London agent is Mr. Henry Pynegar, 5, Dowgate-hill, E.C.

The Glenburn Hydropathic Establishment at Rothesay.—The new Glenburn was formally inaugurated last week. In addition to a full supply of gas, which can be used when necessary, the electric light has been fitted throughout the establishment. Messrs. Claud Hamilton, Limited, of Glasgow, who have lately carried out the electric lighting of the Theatre Royal, Glasgow, and other important work in the Royalty Theatre, Glasgow, and Lyceum Theatre, Edinburgh, for Messrs. Howard and Wyndham, were the contractors with regard to the generating plant. Steam is supplied from one of two Cornish boilers at 80lb. pressure to two of Ransome's high-speed vertical double-acting engines. The engines each drive by belting a compound dynamo.

Londonderry.—The Electric Lighting Committee of the Town Council met on Tuesday to appoint an electrician to take charge of the works. There were 71 applicants for this office. The Corporation had invited Messrs. Siemens to select the three most eligible from that number. The first of these was John Christie, age 26, of the Glasgow electric lighting station, who required £180 to £200 a year; the second was H. C. Kromschroeder, Woolwich, age 36, salary £200, progressive; the last was Albert Barnes, age 30, Exhibition-road, South Kensington, S.W., salary £150. Councillor Brewster proposed that John Christie be elected electrician at a salary of £180 a year. Councillor Young seconded the motion, which, after some discussion, was carried.

Eccles.—On Monday, at a meeting of the Town Council, Alderman Kendall moved the acceptance of the minutes of the Electric Lighting Committee and the terms of Prof. J. Hopkinson to prepare a report upon the electric lighting of Eccles, dealing with the position of the generating station, the system to be adopted, and the extent of the installation. Alderman Spary said he did not think the Council would find it profitable to light the borough with the electric light. He should object to any expense being incurred until the Council knew what number of private consumers would avail themselves of the new light. In reply, Alderman Kendall said that the Council had to make a start if they were to comply with the conditions of the order. Before a scheme was adopted the sanction of the ratepayers would be sought. The resolution was carried.

Plant for Sale.—As stated in our advertisement columns, the London and India Docks Joint Committee are prepared to receive tenders for the purchase (including removal from present sites) of the following: four Marshalls multitubular boilers; four Marshalls single-acting engines, with jet condensers; three vertical donkey pumps; 28 cast-iron standards with plummer blocks; four lengths of steel shafting, each 40ft.; 47 dynamos and seven exciters; 179 arc lamps and lanterns; 44 cast-iron pulleys; 54 lengths of leather belting; sundry carbons; two spare travelling bobbins; four spare commutator rings. The whole of this plant can be seen at the Royal Albert Dock. Tenders must be addressed to the Chairman, Works and Stores Committee, by 31st inst. Further particulars and specifications can be obtained on application at the Dock House, 109, Leadenhall-street, E.C.

The Palace, New Brighton.—Messrs. A. Hall and Co., of 1 and 11, South John-street, Liverpool, have secured the contract for the lighting of the Palace, New Brighton. The plant will consist of a 32-h.p. gas-engine, a 100-light machine, and handsome switchboard; these are to be erected in the grotto which is open to the public. In the large hall they are fitting 106 16-c.p. lamps in handsome electroliers, also lighting the theatre and skating rink attached to the Palace. In all there will be 200 16-c.p. lamps and six large arcs, together with the company's patent electrical signboard illumination. In addition to this, Messrs. Hall and Co. have been favoured with a contract for complete electric light installation, consisting of gas-engine, dynamo, and numerous 16-c.p. incandescent and arc lamps, for Mr. W. Boote, of the City Pantechnicon, Elizabeth-street, Liverpool, for whom they had previously put down a successful installation at another of his establishments.

Newington, Priddle, and Co., Limited.—This Company was formed in March, 1893, to acquire the business of electrical and mechanical engineers carried on by Mr. Newington and Mr. Priddle. The nominal capital of the Company was £7,000, and the purchase price for the business was £4,000, payable in shares. Under a winding-up order made last January against the Company, accounts were issued on Wednesday showing debts £1,210.

Digitized by Google

19s. 10d., ranking against assets £744. 1s. 4d., and a total deficiency of £6,446. 18s. 6d. to the contributories. The sole right to manufacture and sell the "Phonautograph" was acquired by the Company in May, 1893, and a sum of £500 was advanced to the inventor, to be repaid out of the profits on the sales, but no such sales have been effected. To the lock-up of that £500, and to insufficient working capital, the failure of the Company is attributed.

Liverpool.—It is stated that the Health Committee of the Liverpool Corporation decided last week to adopt a plan by which the refuse burnt at the destructor in the sanitary yard at Chisenhale-street will be utilised for the development of power sufficient te light the yard by electricity. The following resolution passed by the Liverpool Trades and Labour Council, and forwarded by Mr. Charles Rouse, the secretary of that body, was referred on Wednesday to the Watch Committee of the Liverpool Town Council for consideration: "That this meeting of the Liverpool and District Trades and Labour Council urge upon the City Council, in view of the present exorbitant price of gas, to consider the possibility of utilising the tidal force for the generation of electricity, thus improving the lighting of the city at a reduced cost to the ratepayers, the construction of the works also affording employment for some of the surplus labour in the market."

Emmanuel College, Cambridge.—The London branch of Messrs. Mather and Platt, Limited, of 16, Victoria-street, Westminster, have recently completed an electric light installation at Emmanuel College, Cambridge. It comprises a semi-portable engine developing 20 b.h.p., driving an Edison-Hopkinson dynamo having an output of 120 amperes at 140 volts. The college buildings being distributed over a considerable area, special arrangements have been made for the distribution of the current, and the equalisation of potential, and underground cables have been run to various centres. A large set of accumulators, capable of discharging at 120 amperes, has been supplied and erected. The cells are of the Electrical Storage Syndicate's chloride make—a type of battery which is now being introduced into England, and which we described a few months ago. Some 300 lights have been erected in the college, the fellows' and masters' chambers, chapel, and lecture-rooms, etc.

Elmore Copper Companies.—Mr. Edward Reynolds, of Vickers, Sons, and Co., Limited, has joined the board of Elmore's Wire Manufacturing Company, Limited. It is stated that the whole of the recent issue of £30,000 preference shares has been placed. A circular issued to the shareholders of Elmore's German and Austro-Hungarian Metal Company, Limited, states: "Your directors regret that the issue of the 8 per cent. debenture stock, offered to the shareholders in their circular of the 10th ult., has not been taken up. This is unfortunate, as it leaves no alternative but to proceed with the issue of the preference shares referred to in that circular. On the other hand, the directors have pleasure in announcing that a contract has been entered into with the German Imperial Marine for the supply, to the Government docks at Wilhelmshaven, Kiel, and Dantzic, of all the copper tubes between 7in. and 12in. in diameter that may be required for the next three years, and it is imperative that the company be at once put in funds in order to carry this contract into effect."

Cheltenham.—At a meeting of the Town Council on Monday, the Electric Lighting Committee recommended that the tender of the Galloway Company for two boilers at £438. 15s. each should be accepted. They also recommended that the quick-running type of engine be adopted, but before finally deciding on the particular engines and alternators the committee thought it desirable to see and inspect the system in operation at Bristol, and that, subject to such inspection being satisfactory, the tender of Messrs. Siemens and Co., with Willans engines, at £4,610, less £365 for boiler, be accepted. Mr. Ward-Humphreys proposed, and Mr. Woodard seconded, the adoption of these recommendations. Mr. Margrett moved that the whole matter be referred back to the committee for further information, and pending the decision of the Local Government Board as to whether sanction would be given to the necessary loan. Mr. Steel seconded the amendment. Eventually the adoption of the minutes was adjourned to allow of further information being given.

Morley.—On Monday the Town Council adopted the report of the Electric Lighting Committee, which stated that various schemes had been considered, and that the committee had visited the electric lighting works at Bradford, Huddersfield, and Leeds. The result of their inspection of the places and schemes is that, in the first place, they recommended that the premium for the best scheme should be awarded to the author of the scheme marked "Lux et Felicitas." This, on being opened by the Mayor, was found to be that of Mr. Robert Hammond. They believed that a thoroughly efficient service of electric lighting, including the provision of land and the necessary works extending from St. Peter's Church to High-street, and including the branch streets, could be established for the sum of £15,000. The system they recommended was high tension. The committee also asked for power to prepare a more detailed report, and ascertain what loans would be required, and to take steps for obtaining the necessary powers to establish the supply as early as practicable, and this was granted.

Lighting of Monmouth.—A special meeting of the Town Council was held on Tuesday of last week to receive the report of Messrs. Bramwell and Harris on the combined scheme for electric light and drainage in the borough, and particularly the practicability or otherwise of utilising the Wye as a motive power to work the machinery by turbines. The report fully approved of the scheme as set forth in the plans prepared by Mr. Lailey, C.E., and the British Electrical Company. They are of opinion, however, that the site selected for the turbines is not the most suitable in view of the great expense of forming a separate watercourse, and some difficulty which has arisen with the owners of land for purification purposes. Having thoroughly inspected the locality, they recommend that the electric generating station be fixed on a now disused watercourse at the Old Forge on the River Monnow, where a continuous supply of water, with a fall of 9ft., can be relied on all the year round. This arrangement would allow of the sewage pumping machinery being fixed at any convenient place, it being worked by electric motors. After discussion the scheme was adjourned until last Monday. The Town Council then agreed that Messrs. Bramwell and Harris should be requested to advise the Corporation generally upon the proper system to be adopted. The clerk was requested to apply for a provisional order for electric lighting.

The Telephone System in Manchester.—Mr. Alderman Milling, chairman of the Paving and Highways Committee, moved on Wednesday, at a meeting of the Town Council, the adoption of the report of the committee with reference to the arrangements proposed to be made with the National Telephone Company for the laying down of the wires of that company under the streets of the city. He said it would be remembered that on the 7th of last month the Paving and Highways Committee received instructions to negotiate with the National Telephone Company with the view of entering into arrangements with the company to take down their sky wires in the centre of the city and lay them under the streets. A sub-committee was appointed, who had an interview with the officials of the National Telephone Company, when the whole matter was thoroughly gone into. The manager, Mr. Gaine, was told that there was a strong feeling on the part of some members of the Corporation that substantial reductions should be made in the annual subscription in consequence of the consideration which the Company had received. Mr. Gaine, however, said it was absolutely impossible. Out of the £10 a year they received from subscribers £8 went in expenses, £1 went to the Government, and the remainder went in dividend and renewals; and therefore there remained a very small margin indeed for the latter purpose. He added that if that line of policy was pursued the negotiations must collapse, because the company could not for a moment recede from the position they had taken up. With regard to equivalents, the company were prepared to pay to the Corporation a charge of 5s. per annum for each subscriber to the Manchester telephone exchange of the company for the privilege of using the streets for the underground tubes; that the minimum number of subscribers to be charged for would be 3,000, which would result at once in an income of £750 a year. They anticipated that there would be obtained 9,000 subscribers, amounting to a sum of £2,250 a year. Mr. Alderman Milling, by means of plans, described the manner in which the wires would be laid underground, and pointed out that no monopoly would be conferred upon the company, because the Corporation would have full power to make arrangements with other companies if it thought fit. The National Company would be responsible for and would indemnify the Corporation against all damages and accidents. He quoted a list of charges made for telephonic accommodation in various continental cities and in America. These ranged from £9. 16s. per annum in Amsterdam to £39. 11s. in St. Petersburg and £50 in New York. After considerable discussion the report of the committee was adopted.

Electric Lighting of Bury.—At a meeting of the Electric Lighting Committee of the County Council on January 23, it was resolved that Messrs. Crompton and Co. should be added to the list of firms to be askod to tender for the carrying out of the scheme of the committee when prepared, and it was also resolved that the committee visit the stations at Liverpool, Bradford, and Leeds before deciding on the scheme to be adopted. At a meeting on February 12 the report on the visits to Leeds, Bradford, and Liverpool was approved. The following report was presented by the borough engineer: "In accordance with your suggestion, sketch plans have been prepared of the electric lighting station, (1) general plan of site showing position of offices, engine-house, boiler-house, condenser pond, etc.; (2) plan showing accumulator, boiler, and engine house, sufficient for the supply of 7,000 8-c.p. lamps; (3) additions showing building for double the number. The plans provided for direct-driven engines, but if the committee decide to adopt rope driving, the only alteration required will be the extending of the west wall to the street line. As previously decided upon, the system proposed to be adopted is continuous current, medium pressure, with accumulators, and three wires for distributing the energy. The pressure at the lamps is proposed to be 110 volts. Plant is proposed to be erected as a first installation of about 4,000 8-c.p. lamps, but the capacity of the building, as already stated, is such as to allow for 7,000 8-c.p. lamps. The following is a brief description of the proposed buildings and plant. The buildings are divided into four parts: (1) the offices, testing-rooms, showrooms, stores, etc.; (2) the accumulator-room; (3) the boiler-house; (4) the engine and dynamo room. The offices are proposed to be built in two storeys upon the narrow strip of land adjoining the site in Rochdale-road. On the ground floor there will be enquiry and clerk's office, space room, common sitting and locker room for employés, store-room for lamps and materials, fitting and repairs shop, cable terminal room, weigh-house, and storekeeper's room. On the first floor there will be engineer's offices, fitting showroom, experimental laboratory and lamp-testing room, meter-testing room, meter storeroom, electrical testing-room for standard instruments. Under the passage running from end to end of the offices will be the main conduit for conveying the cables from the cable terminals room to the street, and a similar conduit leads from the terminals-room into the

Digitized by Google

engine-house and behind the main switchboard. The accumulator-house of special construction without metal as far as possible, and with abundant ventilation, will be fitted with 150 Epstein accumulator cells, fitted to maintain 2,500 lamps for two hours if a total breakdown occurs to the machinery, but will be large enough for double that quantity. The boiler-house to have foundations built for three boilers and a chimney sufficient for six boilers. It is proposed to put down at first two Lancashire boilers, each 30ft. long, 8ft. diameter, for a working pressure of 150lb. per square inch. Steam-pipes to be of wrought iron, with copper bends and connecting pieces to engines. The engine-house to contain, as a first instalment, two engines of 200 i.h.p. each, and one engine of 75 i.h.p., directly connected to slow-speed dynamos. Two dynamos to give an output of 270 volts and 500 amperes. One dynamo to give an output of 280 volts and 200 amperes. The main switchboard to be of enamelled slate to represent green marble, finished in polished walnut mountings. A set of economisers, of Messrs. Lowcock's, Green's, or other approved manufacture. An independent condensing plant of approved make to be placed in the boiler-house. Cables to be of the highest quality obtainable, laid either in cast-iron pipes or troughs, or bitumen or earthenware. All cables to be insulated with vulcanised india-rubber." It was resolved that the report be entered on the minutes, and that plans and specifications be prepared on the lines laid down therein, and submitted to a future meeting of the committee. The Mayor, at a meeting of the County Council last week, moved the confirmation of these minutes. After some discussion, they were confirmed.

PROVISIONAL PATENTS, 1894.

FEBRUARY 26.

4055. **Improved telephone exchange system.** Pierre Emmanuel Emile Raverot and Georges Albert Hess, 1, Rue Boursalt, Paris. (Date applied for under Patents, etc., Act, 1883, Section 103, 8th August, 1893, being date of application in France.)

4083. **Improvements in electric arc lamps.** Karl Schleyder, 323, High Holborn, London. (Complete specification.)

4091. **Appliances for the carbons of electric arc lamps for increasing the duration thereof.** Francis Jehl and Moriz von Hardtmuth, 28, Southampton-buildings, Chancery-lane, London. (Complete specification.)

4096. **Improvements in cable traction operated by electricity as a motive power.** James Lloyd Copping, 1, Queen Victoria-street, London.

4102. **Improvements in street fire-alarms and telephonic combinations for same.** Henry Alfred Charles Saunders and Alfred Charles Brown, Winchester House, Old Broad-street, London.

FEBRUARY 27.

4113. **Improvements in electric batteries.** Harry Theodore Barnett, 14, Narcissus-road, West Hampstead, London.

4142. **Improvements in construction of electrical letters and signs.** Alfred Réné Upward, 150, Holland-road, Kensington, London.

4144. **Improvements in electrodes for arc lamps.** Edgar Oldcott Clark, 55, Chancery-lane, London. (Complete specification.)

4168. **Improved construction of electric battery.** Avando Warren Hussey, 166, Fleet-street, London.

4170. **Improvements in alternating-current electric motors.** William Phillips Thompson, 6, Lord-street, Liverpool. (Charles S. Bradley, United States.)

4171. **Improvements in alternating-current electric motors.** William Phillips Thompson, 6, Lord-street, Liverpool. (Charles S. Bradley, United States.)

4177. **A new or improved reel device for fire hose, electric cables, suspending cords, and the like.** William Phillips Thompson, 6, Lord-street, Liverpool. (Philipp Schneider, Germany.)

4182. **Improvements in overhead electric travelling cranes.** Lloyd Higginbottom, Thomas Mannock, and Edward Hopkinson, Crown Ironworks, West Gorton, Manchester.

4190. **Improvements in apparatus for use with electrically-illuminated signs or advertisements, or in other cases where frequent changes of electric circuits are to be made.** Ernest Lower Berry and Frederick Harrison, 47, Lincoln's-inn-fields, London.

4197. **Improvements in or connected with bases and covers for electric switches and fuses.** Friedrich Wilhelm Busch, Norfolk House, Norfolk-street, Strand, London. (Complete specification.)

FEBRUARY 28.

4214. **Improvements in or in connection with electricity and other meters.** Wilfrid L. Spence, The Elms, Seymour-grove, Manchester.

4226. **Improvements in electric arc lamps.** Rudolf Hermann Jahr and Carl Ferdinand Schoeller, 47, Lincoln's-inn-fields, London.

4235. **A new electric fitting for piano.** John William Ewart, 23, Ampthill-square, London.

4254. **Improvements in electric arc lamps.** John Charles Bond Andrews, 5, Melrose-gardens, London.

4244. **Improvements in and relating to the overhead system of electric tramways.** Alfred Dickinson, 77, Colmore-row, Birmingham. (Complete specification.)

MARCH 1.

4325. **Improvements in the electro-deposition of aluminium.** Alfred Hinton Harris, 128, Colmore-row, Birmingham.

4326. **Lamp, answering the purpose for cap and loop lamp (for incandescent lamps).** Thomas Bamber and Oswald Bamber, 96, Empress-street, Accrington.

4333. **Improvements in and relating to apparatus for supporting and suspending electric light and other like fittings.** William Henry Johnson, Upper Terrace-road, Bournemouth. (Complete specification.)

4353. **Improvements in recorders and reproducers of phonographs.** Alfred Waterman Carter, 22, Glasshouse-street, Regent-street, London.

4366. **Improvements in dynamo-electric machines.** Alfred Julius Boult, 323, High Holborn, London. (Compagnie de l'Industrie Electrique, Switzerland.)

MARCH 2.

4402. **An electricity meter.** Harold George Rea, 22, Cardigan-road, Richmond-hill, Surrey.

4429. **Improvements in and in the manufacture of electrical switches.** Amandus Metzger, 55, Chancery-lane, London. (Complete specification.)

MARCH 3.

4477. **An improved automatic regulator for electric generators.** John Hesketh and Thomas Hesketh, 14, Osbourne-road, South Shore, Blackpool.

4484. **Electromagnetic switching.** George Michaelson, 33, Unter den Linden, Berlin.

4485. **Correction of an electric bell.** George Michaelson, 33, Unter den Linden, Berlin.

4522. **Improvements in electrically-operated clocks.** Alfred Julius Boult, 323, High Holborn, London. (Henri Campiche, Switzerland.) (Complete specification.)

4539. **A joint for wires and electrical conductors.** Wilhelm Dieselhorst and Siemens Bros. and Co., Limited, 28, Southampton-buildings, Chancery-lane, London. (Complete specification.)

4540. **Improvements in contact bars for the overhead conductors of electrical railways and tramways.** Siemens Bros. and Co., Limited, 28, Southampton-buildings, Chancery-lane, London. (Messrs. Siemens and Halske, Germany.)

4554. **Improvement in telephony.** Charles Adams-Randall, 1, The Avenue, Bedford-park, London.

SPECIFICATIONS PUBLISHED.

1886.

8379. **Secondary batteries.** Reckenzaun. (Second edition.)

1889.

18755. **Plates for secondary batteries.** Reckenzaun. (Second edition.)

1890.

4699. **Telephony.** Kellogg. (Second edition.)

1893.

3477. **Galvanic elements.** Nehmer.

3573. **Extracting metals by electricity.** Taussig.

6470. **Electrical measuring instruments.** Mills. (Kennelly.)

7190. **Magnetic parts of electrical apparatus.** New.

8087. **Arc electric lamps.** Brockie.

24392. **Electric motors for vehicles.** Winkler.

24926. **Arranging wires for electric bell, etc., circuits.** Brierley. (Weber and another.)

1894.

135. **Transmitting electric currents.** Pupin.

495. **Transformers for electric currents.** Thompson. (Coffin.)

NOTES.

Traction at Bristol.—Plans are already being prepared for the electric tramway to Kingswood.

Prescott.—The lighting of the town by electricity is now considered by the Local Board to be satisfactory.

Church-Lighting.—The parish church of St. Mary, at Swansea, was lighted by electricity for the first time on Sunday.

Chemical Society.—The annual general meeting of this society will take place on the 22nd inst., commencing at 8 p.m.

Scarborough.—It is intended to light the Spa by electricity, and the current will be obtained from the electric lighting company.

Littlehampton.—Mr. W. E. Hayne, of Western-road, Brighton, has addressed to the Local Board a long letter referring to electric lighting.

Carriage-Lighting.—The Sherborne Electric Installation and Dorset Polytechnic Company, of Sherborne, are now equipping carriages with the electric light.

Dartford.—The Local Board have decided to renew the gas contract for one year only, and at the end of that period to consider the advisability of lighting the town by electricity.

Sydney.—The Military-road tramway, Sydney, having a length of 2 miles 11 chains of single track, is worked with the electric plant which was previously in use on the Randwick-Waverly line.

Book Received. — We have received from MM. Baudry et Compagnie, of 15, Rue des Saint-Pères, Paris, copy of "Traité de Télégraphie Electrique," by M. H. Thomas, telegraph engineer.

Tower-Lighting.—The Wainhouse ornamental tower in the Calder Valley, between Sowerby Bridge and Copley, is illuminated with arc lamps and a powerful search-light which can be seen for miles round.

Royal Institution.—An address on "The Scientific Work of Tyndall" will be delivered this (Friday) evening by the Right Hon. Lord Rayleigh before the Royal Institution of Great Britain, Albemarle-street, Piccadilly, W.

The Question of a Day Load.—An endeavour is being made to induce the Bristol Town Council to utilise their electric lighting plant for supplying current for motive power purposes during the daytime to various factories and workshops.

Madrid Universal Exhibition.—The Department of Science and Art has received, through the Foreign Office, a copy of a despatch from her Majesty's Minister in Madrid announcing that this exhibition will be opened at the end of May this year.

Wolverhampton. — The Board of Trade have approved the system proposed to be adopted for the supply of electrical energy within the borough, and the Local Government Board have formally sanctioned the borrowing of £30,000 for the purpose.

Cheap Motive Power.—The Bradford Town Council on Tuesday confirmed a recommendation of the Gas and Electricity Supply Committee that the price to be charged for current supplied for motive power purposes from April 1 next to October 1 next should be 3½d. per unit.

Mysore.—Direct Government telegraphic communication between Bangalore and Mysore is to be established. Messages from Bangalore to Mysore have hitherto had first to be wired to the head office in Madras and from there communicated to the capital through the Ootacamund office.

Norwegian Submarine Cable. — The Danish-Norwegian telegraph cable between Peterhead and Egersund, in Norway, having broken about 150 miles east of Peterhead, the telegraph company's steamer "H. C. Orsted," of Copenhagen, has now spliced the break.

Engineers and Shipbuilders.—The sixth general meeting of the North-East Coast Institution of Engineers and Shipbuilders will be held to-morrow (Saturday), the 17th inst., in the Athenæum, Church-street, West Hartlepool. A paper on "Oil-engines," by Mr. William Stafford, will be read.

New Borneo Cable.—The Eastern Extension Telegraph Company have agreed to connect Borneo with Labuan by a branch cable, and the directors of the British North Borneo Company have decided to connect the capital of their territory, Sandakan, by telegraph and road across country, a distance of over 200 miles.

Royal Society.—Papers on the following subjects were down for reading yesterday (Thursday) afternoon: By Mr. E. Matthey, "On the Liquidation of Silver-Copper Alloys"; and by Dr. Kerr, F.R.S., "Experiments on a Fundamental Question in Electro-Optics: Reduction of Relative Retardations to Absolute."

Bournemouth.—The Sanitary Committee of the Town Council have received a letter from Mr. J. A. Greenleaves with reference to a form of refuse destructor by the use of which the heat produced can be utilised in the generation of electricity. The committee have instructed the surveyor to visit Halifax to see one in use and to report to the Council.

Abergavenny.—The Gas Committee of the Abergavenny Improvement Commissioners have obtained tenders for a report by an electrical engineer as to the advisability and cost of an electric light station. A number of tenders, ranging from 20 guineas to 100 guineas, was received, and the committee have accepted that of Mr. Manville, at 35 guineas, to include expenses. Mr. Manville has promised his report at an early date.

Lectures.—Mr. H. Somerville, B.Sc., gave on Sunday afternoon at St. George's Hall, Langham-place, a history of the birth and progress of the dynamo. Mr. W. Habgood, managing director of the British Volta Electric Glow Lamp Company, recently delivered at Great Missenden a lecture on "How Electricity is Generated." On the 7th inst., Mr. W. Perren Maycock, M.I.E.E., gave a lecture on "Electricity" before the Whitgift Grammar School, Croydon.

Extension of Mains.—The London County Council have granted permission to the Westminster Electric Supply Corporation to lay mains in Gillingham-street on both sides, and across Vauxhall Bridge-road, and to the House-to-House Electric Supply Company to place mains on the west side of The Grove, between Redcliffe-square and Tregunter-road, in a part of Onslow-gardens, and on the east side of Ashburn-place. Both high and low tension mains are proposed to be used in the latter case.

Lighting of Workhouses.—The Newcastle Guardians have appointed a committee to consider the question of lighting the whole of the workhouse by electricity. Mr. Parsons was invited to visit the workhouse, and reported that there was sufficient motive power in the workhouse to light the premises, after the first cost of installation, at a third of the present cost of lighting. Calculations tend to show, it is said, that after two or three years the substitution of the electric light will effect a saving of £250 per annum.

Digitized by Google

Lighting at Derby.—Mr. Frederick H. Tulloch conducted an enquiry on Tuesday on behalf of the Local Government Board with respect to an application from the Derby Corporation to borrow £5,000 for the purposes of electric lighting. The town clerk explained that the £5,000 required was in addition to the £30,000 already granted, and was required for new machinery and further mains. It was really for extending the lighting of the streets beyond the obligatory area of London-road and Station-street.

Electric Welding of Rails.—It is stated that about 10 per cent. of the electrically welded rails in Boston have broken in service. The experiment proved that a continuous rail, protected by the pavement, shows no ill effect from expansion; but whether the rails broke from contraction or from inherent weakness due to the welding, is yet to be determined. Hereafter the entire end surfaces, including the head, will be united, and care will be exercised not to injure the fibre of the metal or to restrain the expansion due to the heat.

A Question of Expenses.—At the monthly meeting of the Newport County Council on Tuesday, Mr. Wilkinson wished to know why the electric lighting sub-committee had spent £47. 15s. in going to Chelmsford, when Messrs. Crompton offered to invite them and pay the cost. Mr. Parnall, chairman of the committee, replied that the firm did not give the sub-committee an invitation, but that the sub-committee in all these visits concerning the electric light had kept themselves free from any such influence on the part of anybody.

Water Power for Electric Lighting.—The electric light and power station for the town of Chambéry, near Lyons, France, is remarkable for the height of the waterfalls used to drive the turbines. These falls are on the Isère, about 11 miles from Chambéry, and, according to *Engineering*, the total head is 2,010ft. They will furnish about 2,000 h.p. The turbines are to drive seven 120-kilowatt alternate-current dynamos, giving an E.M.F. of 5,000 volts. At the points of distribution the potential will be reduced to 110 volts by transformers.

The Institution.—Mr. Alex. Siemens, the president of the Institution of Electrical Engineers, is to be congratulated for deciding, as he did at the gathering last week, that it would be good policy for the Institution to adopt the practice of the Institution of Civil Engineers and bring the meetings to a close at half-past nine. This was done at the last assembly, and we think that the majority, if not all, of the members of the Institution will appreciate this arrangement, which, it will be remembered, used to obtain, but was allowed to fall into abeyance by the late president.

Electric Lighting in Stirling.—A special meeting of the Stirling Town Council was held on Monday to determine whether the Corporation should apply for a provisional order to supply the burgh with electric lighting. An influential deputation having been heard in favour of the Corporation proceeding with an application to the Board of Trade, Provost Kinross moved a resolution to that effect, which was seconded by Bailie Forrest. Bailie Lawson, seconded by Councillor Macewen, moved an amendment in the negative, and on a division the amendment was carried. This decision annuls a previous resolution of the Council to apply for a provisional order.

Attaching Telephone Wires to Roofs.—A case of considerable interest to telephone companies, and particularly to telephone subscribers, has just been decided in Manchester. The judge, Mr. H. G. Shee, Q.C., ruled that there was no trespass on the part of a contractor in attaching telephone wires to the roof of a building for the use of a tenant, although the tenant only occupied one room in any part of the building. Mr. Shee also decided that the tenant in giving an order for the wires to be attached was acting within his rights, as he was making a reasonable business use of the premises, which had been let to him for business purposes.

Communication with Lightships.—The work of laying the first permanent cable between the shore and a lightship in the Ramsgate district was commenced on Saturday between Kingsgate, near the North Foreland, and the lightship on the Kentish Knock Sand, situated at about 20 miles off the headland. The cable has been laid by the telegraph ship "Monarch," and the cable was connected with the telephone on the lightship on Wednesday. The shore-end connection is with the coastguard at Kingsgate. The next of this dangerous series of sands to be connected is the North Sands Head, one of the Goodwin, with lightships opposite Ramsgate.

Electricity in Copper Mines.—It is announced in Butte, Montana, that electricity is to be used extensively in connection with the development of the copper properties owned by W. A. Clark. The Rothschild brothers are said to have become interested with Mr. Clark, and to have despatched to the ground a representative of a large English electrical machinery works. The plans contemplate the purchase of five electric hoists, nine electric pumps, both for station and sinking purposes, and electric drills. Electric cars will convey the ore from the mines to the smelters, and the handling of the ores by elevators will also be accomplished by the use of electricity.

Search-Lights on Ship Canals.—In a recent issue reference was made to the introduction of search-lights for use on vessels passing along the Manchester Ship Canal. Messrs. Baxendale and Co., of Miller-street, Manchester, who supplied the plant, have received from Captain McLaren, of the steamship "Grampus," a letter concerning the results of the tests of the search-light plant on that vessel. The captain states that the experimental trial of the search-light on board the "Grampus" coming down the Manchester Ship Canal on the night of the 2nd inst. gave great satisfaction. He found it of great service in the navigation of the canal, the passage being performed in a little over five hours, and he recommends it for use on the canal at night.

Royal Meteorological Society. — An ordinary meeting of this society will be held at 25, Great George-street, Westminster, on Wednesday, the 21st inst., at 8 p.m. Papers on the following will be read: "Relation between the Mean Quarterly Temperature and the Death-Rate," by Mr. W. H. Dines, B.A., F.R.Met.Soc.; "Effect on the Readings of the Dry Bulb of the Close Proximity of the Reservoir of the Wet Bulb Thermometer," by Mr. F. Gaster, F.R.Met.Soc.; "Duration and Lateral Extent of Gusts of Wind, and the Measurement of their Intensity," by Mr. W. H. Dines, B.A., F.R.Met.Soc.; "On the Calculation of Photographic Cloud Measurements," by Dr. K. G. Olsson; and on "Sudden Changes of the Barometer in the Hebrides on February 23, 1894," by Mr. R. H. Scott, M.A., F.R.S.

Electric Tramway at Cork.—The Committee of the Privy Council have sanctioned a tramway scheme for the city of Cork. The proposed tramways will connect the new station of the Great Southern and Western Railway Company with the Cork and Muskerry Railway Company's station. The Great Southern and Western Railway Company would contribute £2,000 towards the capital of the Cork City Tramways Company, and the Cork Steamship

Digitized by Google

Company would also contribute. It is proposed to work the tramways by electricity. The directors of the company include Mr. Payne-Sheares, chairman of the Cork and Bandon Railway Company; the High Sheriff of the city of Cork; and the President of the Chamber of Commerce, Cork. The Harbour Commissioners have consented to a line passing over Parnell Bridge.

Taunton.—The Electric Lighting Committee of the Town Council reported on Tuesday that the works in connection with the extensions were progressing favourably. The engine and boiler had been received and fixed, and would shortly be ready for use. Several fresh applications had been received for installations, and the necessary connections were being made to supply current from the low-tension main. The committee further reported that Mr. J. A. Robinson, of the Great Western Railway, was about to leave Taunton, and they asked the Council to vote to them a sum, not exceeding £5. 5s., to be expended by them in the purchase of a small present, in recognition of the valuable advice and assistance rendered by him in connection with the carrying on of the electric lighting works during a period of great difficulty and anxiety to the committee. This proposal was agreed to.

Early Notions.—In the beatification of Scriblerus, as described in Cambridge's poem, electric fires are referred to, as is M. Bose's treatise "De Electricitate Inflammante et Beatificante." The action of beatification of Scriblerus seems to have consisted in "charging" him by means of a static machine. It reads:

> And now the glass by streng attrition urg'd,
> First the foul atmosphere around him purg'd;
> Then at the hero's feet began to play
> A flame more brilliant than the solar ray—
> The golden beams ascending now embrac'd
> Th' illustrious sage, and circle round his waist;
> Now fixt, and by increas'd effluvia fed,
> Diffused a glory from his awful head.
> Thus as he darts around electric fire,
> To vocal hymns they tune the sounding lyre;
> His high achievements in their songs relate,
> And hail him monarch of the hermetic state.

Who was Bose, or Bossius, as Cambridge calls him?

Electric Lighting of School Board Offices.—An example of combined lighting and warming is afforded by a complete electrical plant which has recently been put down at the offices of the London School Board on the Victoria-embankment. The plant, which is arranged in the basement of the new buildings, consists of two Babcock-Wilcox water-tube boilers, designed to work at a pressure of 150lb. per square inch. These boilers supply steam to a pair of Parsons combined steam-turbines and dynamos, the turbines being of the radial-flow type, and each of the dynamos being capable of supplying 32,000 watts. Adjoining the engine-room is an accumulator-room, in which there is a battery of storage cells for the electric current. The current is supplied to 1,000 incandescent lamps which are distributed throughout the buildings. The heating of the building is effected by means of the exhaust steam from the engines.

Electric Traction at Dublin.—Mr. George White, chairman of the Imperial Tramways Company, mentioned at a meeting of the latter on Saturday, that the report touched upon the important subject of the introduction on the company's lines of electric traction. He said that they had a continuous line of eight miles of tramway running from Dublin through Blackrock and Kingstown to Dalkey, and that the installation of electric traction was looked forward to with pleasure by the authorities, who foresaw the advantages which must result to the district in thus securing what would practically be a line of railway with all the advantages of speed and easy locomotion, without the disadvantages of the noise and smoke attending the ordinary railway. The company were the first possessing absolute parliamentary authority to use the overhead system in Ireland, and they believed that the negotiations they were entering upon would be attended with benefit to the Dublin Southern District Tramways Company.

Milde Telephone Company.—The prospectus has been issued of the Mildé Telephones and Electric Supply Company, Limited. The capital is £20,000, in 15,000 7 per cent. cumulative preference shares and 5,000 deferred shares of £1 each. Subscriptions are now invited for the preference shares. The Company has been formed with the object of acquiring the sole rights granted to Mr. M. Kotyra by Messrs. Ch. Mildé, Fils, and Co., of Paris, to sell their telephones in Great Britain and Ireland and the English Colonies; to establish local, provincial, and private telephone exchanges, and to carry on other branches of electrical work. Mr. Kotyra has been manager for Messrs. Mildé's works in Paris for many years, and he has now taken up the sole agency in this country. These rights Mr. Kotyra proposes to sell to the Company for the 5,000 deferred shares, and he has entered into an agreement to remain general manager of the Company for a term of three years. The offices of the company are at 60, Watling-street, E.C.

Electricity in Mining.—At a meeting of the North Staffordshire Mining Institute at Stoke on Monday evening, Mr. J. Vaughan Hughes, Assoc.R.S.M., read some remarks on a paper previously read by Mr. R. H. Wynne on "The Application of Mechanical Arrangements in Underground Operations." Mr. Hughes showed several diagrams and tabulated statements setting forth results obtained by the use of compressed air, gas, steam, and electrical energy. Mr. Wynne criticised the remarks of Mr. Hughes, especially as to the use of gas underground, and said he was halting as to whether electricity or compressed air was the best to apply for some secondary kind of power. Electricity would be quite inapplicable for long distances underground. Mr. E. B. Wain maintained that in North Staffordshire mines, where there were such varying circumstances, horse power was the best for haulage. Mr. J. J. Prest agreed very much with Mr. Wain as to horse power, and said with regard to electricity he did not think it would come into general use in mines so much as compressed air.

Personal.—We tender our congratulations to Mr. T. Caink, assistant surveyor, who has been appointed engineer and surveyor to the Worcester Town Council. Mr. Caink is the patentee of an improved form of gravity battery in which broken carbon is substituted for the sand or sawdust previously adopted, by which the internal resistance of the cell is greatly diminished; the patent also covers a special syphon for removing and recharging the liquids. He is likewise the patentee of a method of simultaneous lighting and extinguishing street lamps by electricity, by which temporary increase in the pressure in the mains closes for a few seconds an electrical circuit at the same instant that it opens the gas-way to the burner. At a meeting of the Chemical Society on the 1st inst. a certificate was read in favour of Mr. James Swinburne. Mr. C. H. Wordingham, A.M.I.C.E., has accepted the position of chief engineer to the Manchester Corporation electric works, at the invitation of the Electric Lighting Committee. Mr. Wordingham superintended the carrying out of the several contracts for the establishment of the central stations at Manchester and Whitehaven on behalf of Dr. Hopkinson, and has been running the Manchester station during the last three months.

"The Universal (J. A. Berly's) Electrical Directory."—A copy of this directory for the current year has reached us from Messrs. Alabaster, Gatehouse, and Co., of

Digitized by Google

22, Paternoster-row, E.C. The directory comprises the names of the members of the electrical and kindred fraternities throughout the world, and the amount of work entailed in its compilation will be readily understood when it is mentioned that the British sections contain about 16,386 names, the continental sections 13,880, the American sections 9,370, and the colonial sections 2,155 names, being a total of 41,791 entries, many of which appear more than once. There are, however, approximately 18,414 names of different individuals and firms contained in the book. For simplicity and facility of reference the directory is divided into the four groups mentioned—namely, British, Continental, American, and Colonial. These are again subdivided into alphabetical and classified sections. The new names incorporated in the present issue number several thousands, and the total pages added to the work is 104 as compared with that of 1893, making in all about 800 pages of directory matter. The directory is the largest and the oldest electrical directory in the world, and the price is 4s., as on previous occasions.

Willans and Robinson, Limited.—As will be seen from our advertisement columns, the business of Messrs. Willans and Robinson, Limited, which was converted into a private company in 1888, is now being transformed into a public limited company. The Company's business in the construction of steam-engines has been carried on with large success at Thames Ditton, Surrey, for 13 years, and the Willans engines are known throughout the whole world as being economical in working and having a high rate of efficiency. The capital of the Company is £300,000 divided into 30,000 6 per cent. cumulative preference shares of £5 each, and 30,000 ordinary shares of £5 each. The present issue for which subscriptions are invited comprises 8,037 preference and 8,038 ordinary shares. With regard to the remainder, 14,463 preference and 14,462 ordinary shares will be alloted in part payment of purchase-money, while 7,500 shares of each class are reserved for future issue. The large increase in the Company's business has necessitated considerable extensions in the works and plant, and the Company has therefore been reconstructed on a wider basis. The subscription lists will close on or before Wednesday next, the 21st inst., for London, and on Thursday for the country.

Reverberatory Furnace with Movable Electrodes.—In the *Compt. Rend.* M. Moissan describes a reverberatory furnace with movable electrodes. The furnace consists of a parallelopiped of Courson limestone, in which is cut a somewhat large cavity, also a parallelopiped in shape, which is lined with alternate plates of magnesia and carbon, about 10mm. thick, so arranged that magnesia is in contact with the limestone, whilst carbon forms the internal lining of the cavity. A lid, of alternate plates of magnesia and carbon, covers the cavity, and a block of Courson limestone is placed above this lid. The electrodes are movable, and pass through slots cut in opposite sides of the furnace. At right angles to the electrodes a carbon tube, 10mm. to 20mm. in diameter, passes through the furnace, and is so arranged as to be 10mm. below the arc and 10mm. above the bottom of the cavity. If necessary, the tube can be lined with magnesia. By inclining the tube at an angle of about 30deg., the furnace can be made to work continuously, the reducible material being introduced at the higher end, whilst the product of reduction is drawn off at the lower end. With a current of 600 amperes and 60 volts, two kilos of fused metallic chromium can be obtained in about an hour, the metal being received in a crucible made of chromic oxide. The metal is white, finely granular, and very hard, and takes a high polish. The magnesia is prepared by heating strongly the basic carbonate, digesting the product with ammonium carbonate solution, and again strongly heating. It is then moistened with water and compressed. With this furnace silicon carbide and vanadium carbide can be readily obtained by the direct combination of carbon vapour with the vapours of silicon and vanadium.

Low-Frequency Alternating Current.—Referring to the low-frequency alternate current—25 per second—adopted at Niagara Falls, Mr. William Stanly, jun., in a recent article in the *Electrical World*, shows that for the transmission of power the use of very low frequencies is not justified, and he intends to show why such a procedure is bad engineering from the transformer standpoint. To sum up the virtues of high-frequency motors, we have, according to the author's calculations, first, a greater torque at all times for the material employed, and consequently a greater output; second, a lower impedance armature and a lower inductance in the armature circuit, consequently for a given load a smaller armature current; third, a smaller armature reaction and "blowing out" effect produced by armature reaction. The experience at Pittsfield, where for 15 months two-phase motors whose magnetising currents are supplied from condensers have been in operation, is a sufficient proof of the practical operation of condensers. These motors are operating at 130 periods per second. They are connected to all classes of work, operating, as they do, a sawmill, a woollen factory, machine shops, a printing office, etc., and it has been found, by actual observations of the voltmeter in circuit on the consumers' premises, that the variation of potential due to changes of load and lag on the motors does not average 2 per cent. of the voltage applied. The regulation of these circuits is as perfect as if they were simply operating lamps alone.

The Proposed British Pacific Cable.—At the meeting of the Intercolonial Postal Conference on Thursday of last week, at Wellington, the debate was resumed on the motion submitted by Mr. J. G. Ward, the president, recommending the Governments of the various colonies to consider the desirability of entering into an agreement with the other countries concerned in the enterprise to guarantee the interest, at the rate of 4 per cent. per annum, on a capital of not more than £1,800,000, to any company undertaking to lay a Pacific cable, provided the tariff charge does not exceed 3s. per word for ordinary telegrams, 2s. per word for Government telegrams, and 1s. 6d. per word for Press telegrams to and from Great Britain and the colonies. The motion was discussed at great length and eventually adopted. Mr. A. Wynne, the Postmaster-General of Victoria, declared during the deliberations that his colony was satisfied with the present cable; but that, if the whole of the colonies and the Imperial Government agreed to pay their proportion of the guarantee, he would support the scheme. Mr. W. H. Wilson, Postmaster-General of Queensland, announced that he was in thorough accord with the motion, and that the Government of Queensland would do everything in its power to help the promoters to carry the project to a successful issue. Dr. J. A. Cockburn, the representative of South Australia, and the Postmaster-General of Western Australia, announced that they were unable to vote on the question. Mr. James Inglis, formerly Minister of Education of New South Wales, who is now in London, is keenly interested, as chairman of the Sydney Chamber of Commerce, in the proceedings of the Australasian Postal Conference. He stated that it was immaterial to New South Wales whether the cable started from Queensland or New Zealand; but the eastern colonies of Australia certainly felt that a second cable was needed. New South Wales had been committed to the New Caledonian project before

Digitized by Google

Parliament was consulted, and she would not repudiate her obligations, although they involved an expenditure of something like £60,000. It was highly improbable that a Pacific cable which passed through the territory of a foreign Power would commend itself to the people of Australia or New Zealand. As approved by the Postal Conference, the cable would touch at no point outside British influence.

Lighting of the Victoria-Embankment.—It will be remembered, as stated in our last issue, that the London County Council postponed the consideration of a report by the Highways Committee concerning the electric lighting of the Victoria-embankment. As will be recollected, the Council on the 13th ult. referred back to the Highways Committee a recommendation which they then submitted regarding the laying of the conduits and the formation of refuges around the lamp columns in connection with the electric lighting of the Victoria-embankment, objection having been raised to the proposal to place the columns in the centre of the roadway. On Tuesday, the committee thought it well to give some of the reasons upon which they based their opinion that the best arrangement for lighting the embankment is for the lamps to be placed in the centre of the carriageway. They stated that: "If the electric lamps were to be placed along the kerb on each side of the carriageway it would be necessary either (*a*) to use very lofty columns for the lamps, or (*b*) to cut the trees in order to allow of the lamps being fixed in the desired positions. Should the former alternative be adopted, the trees would still veil the light from large portions of the road and footways, while the adoption of the second would involve a mutilation of the trees, which would greatly detract from the picturesque appearance of the embankment. In some of the continental cities the lamps are suspended by means of wires or cables; and this method necessitates the placing of standards in the carriageway to support the wires, except in the case of narrow streets where other means are adopted. Should these necessary supports be placed on the embankment against the kerbs, the span would be so great, on account of the width of the carriageway, that the lamps would be unsteady in the slightest breeze, and this would seriously diminish the effectiveness of the light. Owing to the width of the road it would be almost impossible, and certainly unadvisable, to erect arches or fix girders on standards for the purpose of carrying the lamps." Having again given careful consideration to the matter, the committee came to the conclusion that the least objectionable and the most advantageous method of distributing the light over the embankment would be by the erection of ornamental lamp columns, each with a small refuge round it, not exceeding 4ft. in width, in the centre of the carriageway. This is at no part less than 64ft. in width from kerb to kerb, and there would be left on each side of the refuges a space of 30ft. The committee saw no reason for altering the recommendation which was referred back to them on 13th ult., which they again submitted. The committee therefore recommended that, subject to an estimate being submitted to the Council by the Finance Committee, the work of laying the necessary conduits and the forming of the refuges round the lamp columns in connection with the electric light installation for the Victoria-embankment, etc., should be carried out by the Council without the intervention of a contractor; and that the plans, specification, and estimate should be referred to the Works Committee for that purpose. A long discussion ensued upon this proposal, and in the end the Council expressed the opinion that it was undesirable to erect lamp columns in the centre of the roadway.

Determination of Electrical Resistance by Alternating Currents.—In the "Foreign Abstracts" of the Institution of Electrical Engineers is given a summary of an article by Prof. F. Kohlrausch published on this subject in *Wiedemann's Annalen*. This article is an amplification of the author's former work on the subject, in which he communicates the results of his experiments on the conditions of accuracy and trustworthiness of the method which he has introduced. He is of opinion that the difficulties, uncertainties, and the small differences which sometimes occur in the determination of the resistance of electrolytes by means of alternating currents are due more to chemical than to electrical causes, and to the influence of temperature. The author's apparatus consisted of a Hartmann and Braun induction coil, with a platinum and quicksilver break under distilled water, working at about 85 interruptions per minute, and having 5 and 30 ohms resistance in the two coils; and the rest was as described in the former article. . The results were as follows: The accuracy of the placing of the bridge contact was 1 in 10,000 under favourable circumstances; and if the position of minimum sound is indefinite, owing to polarisation, self-induction, or capacity, the determination of the mid-point between two positions of similar amount of sound gives the resistance nearly correctly. Chaperon has introduced for telephone work a method of winding resistance coils up to 30,000 ohms; but for ordinary resistance coils it was found that up to 1,000 ohms they might be used with impunity, and up to 4,000 ohms the errors were $\frac{1}{3}$ per cent. and more. Wien states that the error varies as the square of the resistance and the capacity, and the coils for large resistances should be subdivided, rather than wound all on the one bobbin, as the capacity is thereby diminished; and the use of a condenser in shunt to large resistances is recommended. The preparation of sufficiently inductionless coils is not difficult. The error due to polarisation diminishes with the size of the electrode and the resistance: platinum electrodes of 10 and 35 square centimetres surface respectively in cells having resistance of 8 or 25 ohms, gave error of 3 or 1 per cent., and 1 and $\frac{1}{3}$ per cent. differences in telephone and induction coil seemed to have no observable effect. If the product of surface and resistance be 250 ohm-square centimetres or more, the error which may be anticipated will not exceed 1 per cent. In using platinised electrodes a good coat of dull platinum must be used. Sine currents are much more influenced by polarisation. When large resistances are to be measured, special precautions must be taken; as, for instance, inductive effects of coil on bridge and telephone, which must be avoided by suitable means. In the case of water and very dilute solutions the electrostatic capacity of the liquid cell, which is proportional to the specific inductive capacity and the specific resistance of the liquid, disturbs the minimum; but this effect is not serious, and should not introduce 1 per cent. error. When the resistances are of the order a hundred thousand ohms, the disturbances in the telephone due to static charges become annoying; but they can often be removed or mitigated by a suitable earth connection; but with resistances of the order megohms, the errors may amount to several per cent. Other small difficulties are due, in the water bath, to charges on the sides, and these increase as the size increases; they did not occur in a petroleum bath. A want of symmetry in the telephone sometimes occurs with large resistances, and is probably due to static charges. In such a case the telephone must be reversed and held in similar position, and the mean contact point used. This effect seemed to be greater with an induction coil having laminated core than with one having a metal tube over its core.

PRIVATE ELECTRICAL ENTERPRISE IN CHELTENHAM.

The economical utilisation of spare power is a problem which always has a great fascination for mechanical engineers; but to the electrical engineer it is of far greater importance, as it may enable him to perform work which otherwise would be quite out of the question, owing to the initial cost of the requisite motive power. In very many manufactories in this country, such as breweries, etc., where an engine of considerable power is required for actuating grinding mills, pumping plant, hauling apparatus, and similar contrivances, it is absolutely essential that the power be such that it will be capable of doing the work at all times, even when the whole of these appliances are in use simultaneously. Considering the character of the operations in such an establishment it follows that during a day's work there must be intervals when there is a considerable amount of spare power available. It is a well-known fact that an engine gives a far greater efficiency when working at full load than when working with a light load, and it is therefore desirable to increase the load factor as much as possible so as to produce a maximum economy in working. By the employment of a system of electrical storage it is quite easy to convert an intermittent and irregularly generated current into one of perfect regularity. When utilising storage batteries it becomes possible to convert and store electrical energy produced intermittently during a day's working, and to use it at night as a constant supply for illumination and other purposes.

As an example of the successful utilisation of spare power, an installation in Cheltenham which has just been partly completed may be cited. The Cheltenham Original Brewery have placed in the hands of the Lithanode and General Electric Company, of London, the work of lighting their brewery works, the offices and manager's house, and the adjoining Fleece Hotel. Part of this work has now been completed, and on Thursday evening in last week the current was turned on in the Fleece Hotel, the manager's house, and the brewery offices. The work in question has turned out a thorough success, and those who were invited to see the light put on expressed great admiration at its steadiness and the effective way in which all the rooms in the hotel were illuminated.

The general manager of the Lithanode Company, Mr. J. T. Niblett, in conjunction with the proprietor of the hotel, Mr. Hart, made the opening ceremony the occasion for exhibiting a number of interesting appliances, all actuated by electricity. In one of the stock-rooms were shown electric cooking utensils, such as frying-pans, stew-pans, etc., also electrical devices for heating curling-irons, boiling shaving water, and working cigar-lighters and similar appliances. The reconversion of electrical energy into motive power was demonstrated by an electromotor, which was made to propel a ventilating fan, used to ventilate and perfume the room. Among other electrical contrivances shown were carriage and brougham lamps, 'bus and tramcar lighting apparatus, together with a good assortment of lithanode hand-lamps, miners' lamps, etc. Perhaps one of the most telling features of this little exhibition was some electrically-lighted artificial flowers, which attracted much attention and admiration, especially among the ladies.

The Fleece Hotel is the first hotel in Cheltenham to be lighted by electricity. The building is one of those old-fashioned posting-houses now fast disappearing, and consequently, although the house is exceedingly roomy and well-appointed, yet the ceilings in some of the apartments are somewhat low-pitched; and, consequently, when the gas was in use some inconvenience was occasionally experienced from the overheated condition of the apartments. On the substitution of the electric light a marked improvement was observable in the state of the atmosphere, not only in the commercial and other public rooms, but also in all parts of the house.

The proprietor of the hotel is not a man of half measures, and in addition to all the usual offices, billiard-room, smoke-room, writing-room, commercial and coffee rooms, and all the bedrooms, he has had all the corridors and passages and even the pantries and lavatories lighted up by electricity. The hotel contains, among its other accommodations, seven or eight very large stock-rooms; in fact, some of these are said to be the largest in the county. In the stock-rooms the introduction of the electric light has effected a very marked improvement, and the new light will doubtless be greatly appreciated by commercial gentlemen visiting this hotel.

As previously stated, only part of the installation is now finished, but when completed the installation will comprise between 500 and 600 lamps of varying candle-power. The storage batteries used in this installation are an important factor, and these will have a capacity of about 1,200 ampere-hours, and will be capable of running the whole of the lights in the installation for a period of 10 hours when once charged. The accumulators are of the lithanode type, and have been specially made by the Lithanode Company for this installation. The generating and storage plant is in duplicate, there being two dynamos and two sets of accumulators. By the utilisation of a variable resistance in the shunt circuit of the dynamos it is possible to run the lamps direct, either from one or both machines; and by a suitable alteration of the resistance the potential may be raised sufficiently high to charge the accumulators. Arrangements are also made on the switch-board for running one or both dynamos in parallel with one or both sets of accumulators if at any time it is found necessary to do so. The potential of the discharging circuit is 100 volts, and by the employment of two dynamos the generation of the electrical energy may be arranged to suit the load on the engine at any particular time of the day; and as the light may be obtained either from the accumulators separately or conjointly with the dynamos, it follows that the possibility of a complete breakdown is reduced to a minimum.

The engine used by the brewery is one of Savory's, and is of the horizontal type. It is a slow-speed engine of the type usually employed in breweries for pumping and hauling, and is nominally of 30 h.p. To increase the speed a countershaft is used, and this countershaft is propelled from a large driving pulley placed on the main shaft of the engine. The dynamos are of Messrs. Crompton and Co.'s make, and when revolving at their full speed—viz., 1,600 revolutions per minute—are each capable of developing 135 volts and 40 amperes.

The switchboard, placed in the engine house, which controls all sections of the installation, although it has to perform a number of functions, is exceedingly simple in construction. Two double-pole switches and fuses are placed on the board, and these are arranged so as to cut in or out the dynamo and battery circuits. Two of Lord Kelvin's ampere-gauges are used, one being placed in the charging and the other in the discharging circuit, so that both factors can be read off simultaneously. To prevent a back rush of current through the dynamos an automatic cut-out is of course used. One of Lord Kelvin's multicellular voltmeters is employed for indicating potentials; and by the use of an ingenious and simple switch the voltmeter can be used for testing the potential of the lighting circuit, the potential of the charging circuit, the charging circuit for either battery, the pressure of the batteries themselves, and also the electrical pressure being developed by each dynamo, or the pressure of the lamp circuit. Near the switchboard, and on a level with it, is placed a lever actuating a stepping-up switch placed in the battery-room, which is situated just above the dynamo-room. By this arrangement the engine-driver need not leave his engine-room when making any necessary change in the arrangements of the circuits, and he can also regulate the potential of his discharging circuit by throwing cells in or out. As a means of checking the consumption of electrical energy in the hotel, one of Lord Kelvin's latest type of electricity meter is used. This meter is placed in the cashier's office, which is centrally situated in the building. The supply mains run direct to the meter, and from there they rise to the top of the house, distributing-boards being employed for each floor. The electrical installation in question is being carried out by Mr. M. Sutherland, the Lithanode Company's electrical engineer.

Digitized by Google

A similar installation, but of somewhat smaller dimensions, was carried out some time ago by the Lithanode and General Electric Company at the Gresley Brewery, near Burton-on-Trent. This somewhat novel installation has been in successful operation for a period of over six months, and was carried out by the Lithanode Company's representative, Mr. E. G. Fishenden. In this instance also, the spare power obtained from the pumping-engine is utilised to charge accumulators. As a result, the Gresley Brewery is now being effectively lighted throughout at a very nominal cost—the cost, in fact, only being the interest on the invested capital with the addition of a small sum per annum which must be allowed for depreciation.

NORTHERN SOCIETY OF ELECTRICAL ENGINEERS.

The second meeting of this society was held at Manchester last Monday, when the two papers given below were read and then discussed by Messrs. Wordingham, A. B. Mountain, W. Fox Bourne, J. Conolly, E. W. Cowan, L. Andrew, and R. Taylor—the discussion then being adjourned to the next meeting, to be held on Monday, April 9, though previous to that a smoking concert, the second of the series, is to be held on Monday, April 2.

At the meeting the following new members were elected: Geo. Broughall, Manchester Edison-Swan Company; T. B. C. Nuttall, Siemens Bros., London; A. Oughterson, Messrs. W. T. Glover and Co., Manchester; F. A. Pocklington, Callender Bitumen Company, Liverpool; R. P. Wilson, Wilson and Clirehugh, London.

Notes on Designing a System of Underground Electric Light Mains.

BY JOHN H. RIDER.

The importance of a satisfactory system of underground mains in a scheme for town-lighting may be estimated when we consider that in generating the electricity we have only done half the work. We have still to convey it to the consumers, and in many cases this means to distribute it over a wide area. The difficulties met with in so doing have given rise to the various systems of "high and low tension," and of "continuous and alternating currents," which have been so much discussed by electrical engineers. It is not my intention, however, to dwell on these points, but rather to offer some observations on underground mains generally.

At whatever pressure we may generate our electricity, we are compelled by law to deliver it to our customers at a low pressure. In the case of a general low-pressure system, this is done by means of a distributing network, fed at various points by feeder cables. When the generation is at high pressure, we may use either a low-pressure distributing network, fed through transformers at various points, or we may place transformers on the consumers' premises, and so have practically no low-pressure network at all. The Board of Trade, however, will now only give its sanction for this latter course on the distinct understanding that, when called upon to do so by them, a low-pressure distributing main will be laid down and the house transformers removed. Therefore all arrangements using house transformers can only be looked upon as of a temporary nature.

At the outset we should make a radical distinction between "distributing mains" and "feeders."

"Distributing mains" are those from which the services to the houses are taken. It is therefore necessary to have them of such a cross-section that the fall in pressure from any feeding point to the farthest service on that section does not exceed, say, 2 per cent. when all the lamps are burning. Then, if we keep the various feeding points at a uniform pressure, we may be certain that the whole of the distributing network has a voltage within 2 per cent. of this. In the case of an ordinary business street, it will be found necessary to have the feeding points at not greater than about 250 yards apart, in order to have the distributing mains of a reasonable size.

"Feeders" are mains going direct from the station to the various feeding points, and their use is to feed the distributing network through transformers or otherwise. While we may take more than one feeder to any feeding centre, yet in no case should we arrange any one feeder to supply more than one feeding centre. We should find it impossible to keep the voltage constant all over our distributing network, if we did so. The pressure at the feeding centres must be kept constant by raising the pressure of the several feeders at the station, in proportion to the current flowing through them. As it is impossible to say that the demand for current will always be equal all over the network, it will be necessary to regulate each feeder independently of the others. On direct-current systems this means raising the pressure of the dynamos when the load comes on, and, when the feeders are supplied from omnibus bars, having a regulating resistance in each feeder.

On alternating-current systems the pressure of the machines need not be altered, as the necessary voltage may be added to the feeders by means of adjustable transformers in series with them. The most satisfactory method of indicating at the station the voltage at the different feeding centres is to run back pilot wires from each, and to connect them to voltmeters on the switchboard. The attendant has then simply to regulate for constant volts, and the current in each feeder will take care of itself. In all cases the pilot wires should be connected to the low-pressure network, and not to the high-pressure side of the transformers, as has been done in some alternating-current stations. As the feeders in many cases will be long, we must allow a much greater fall of pressure in them at full load than in the distributing mains. It no longer becomes necessary to keep an approximately even pressure over their whole length, as we do not take service wires from them. In many low-pressure systems a drop of from 10 to 20 per cent. at full load is allowed, and this of course has to be met at the station by an equal increase in order to keep the pressure constant at the feeding centres. If we use larger feeders we shall have less drop, and if smaller then greater drop.

Lord Kelvin's rule is generally quoted in this case—viz., that the maximum economy is obtained when the annual interest on the cost of the feeders equals the annual cost of the energy wasted in them. But it must not be forgotten that small feeders and a large loss also mean larger plant, in consequence of the increased pressure required. This will go to make the cost of the wasted energy higher.

We may divide the many systems of laying mains into two chief classes, "drawn in" and "built in." By the former I mean those which are drawn into pipes or conduits, and by the latter those which are either laid direct in the ground, such as armoured cables, or run in solid with bitumen, etc., such as Callender's solid system. Each class has its advantages and disadvantages, which are, however, much modified when applied to both feeders and distributing mains.

The chief advantages of a "drawn in" system are: (1) easy to inspect, (2) easy to add cables, (3) easy to withdraw cables. As a "drawn in" system generally requires more inspection than a "built in" one, it provides its own remedy. In order that cables may be easily added, it is essential that the conduit should be made large enough, or that spare pipes should be provided. This tends to increase the prime cost. When a "drawn in" system is used for the distributing mains, and service branches are taken off, it becomes impossible to remove the cables without first disconnecting all the consumers. For feeders, however, as no branches are taken off, this is no drawback.

The "built in" systems have the advantages of: (1) generally requiring less space, (2) being easier to lay, (3) no danger from gas or water, (4) less prime cost. Their chief disadvantage lies in our being unable to increase them without reopening the streets.

For low-pressure distributing mains, this disadvantage need not be one at all; for if these mains be calculated with reasonable care for the requirements of the district, they should rarely require enlarging. And if at some future time a greater demand comes at one point than the cables can carry, the simplest way is to run another feeder to that point, and to leave the low-pressure network as it

Digitized by Google

was. This, of course, means that the feeders should be laid on a "drawn in" system.

I venture to think that a combined system of "drawn in" for the feeders, and "built in" for the distributing mains, offers a number of advantages. The distributing mains should only require extending in order to light new streets, and opening the ground may be therefore allowed. But new feeders have in many cases to be taken through streets already lighted in order to reach the new districts, and so they should be "drawn in" to avoid opening the same streets a second time. Opening the streets is such a nuisance to everybody, besides being very expensive, that this point is well worth consideration. Judging from recent experiences, a considerable difficulty in connection with a "drawn in" system, is the danger from gas explosions. There can be little doubt that the gas comes from leaky or broken gas-pipes in the vicinity of the conduit. It is useless to look to the gas companies to lay their mains so that leakage would become impossible. An unlooked-for subsidence of the soil may cause a drawn joint or broken pipe, and it then only requires a spark to complete the mischief. A thorough ventilation of all electric pipes, conduits, and manholes, together with great care in the laying and subsequent inspection, seems the only way to minimise the risks. The perfect freedom of an armoured cable system laid direct in the ground from such accidents is without doubt a very strong point in their favour. In most "drawn in" and in some "built in" systems it is necessary to either make service-boxes opposite the houses as the cables are laid, or else to build such boxes with iron pavement covers when required. Both are expensive methods. But with an armoured cable we need make no preparation for future service connections. Each case is dealt with as it arises, and by the use of a small split junction-box of cast iron placed around the cable, and afterwards filled up with insulating materials, the joints can be well and cheaply made.

So far what has been said will apply with equal force to either continuous or alternating current systems. But alternating-current mains require special precaution to be taken in their design, which need not be considered at all in the case of those for continuous currents. Any current of an alternating or varying character flowing in any conductor will set up E.M.F.'s in neighbouring conductors, and as a result of these E.M.F.'s currents will flow depending in strength upon the resistances encountered. It is most essential that adjacent wires should be protected from such currents, and the remedy that suggests itself is to entirely surround the alternating-current conductors by a metallic sheathing, such as an iron or a lead covering. This, however, would only remove the disturbances from the neighbouring wires to the sheathing itself. It would not prevent them altogether, but may, in fact, increase them, and so cause a great waste of energy. To stop them, it would become necessary to place both the flow and return conductors within the same pipe or sheathing, and if the system were a three-wire one, then all three wires must be so treated. A perfect cure is only obtained when the conductors are so placed with respect to the pipe or sheathing that their centres are practically coincident. A concentric cable meets this condition, either when drawn into an iron pipe, or when lead-covered and armoured. I believe many alternating-current systems are working where this precaution is more or less disregarded, and the amount of power lost through waste currents is unknown. Considering that these losses are going on all the time the station is running, they must amount to a good deal in the course of a year, and in some cases may probably equal the magnetising current losses of the transformers. It would appear that this question is either not understood or else ignored by many who have to design alternating-current mains. In a recent case it was specified by a well-known engineer, that three separate lead-covered cables were to be used for a three-wire alternating system. In the scheme which I am at present carrying out, the actual arrangement for the low-tension mains was left open, so that every contractor might tender on his own lines and for his own system. It was distinctly pointed out that alternating currents were to be used on the three-wire system, and yet out of 20 different offers no less than nine had entirely overlooked the question of induced currents. Some firms proposed to use separate lead-covered cables, drawn into cast-iron pipes. Others offered separate lead-covered and armoured cables, to be laid direct in the ground. Others, again, proposed to use two concentric armoured cables, the middle wire of the system being divided and placed half in each cable. Of course, when the loads on the two sides of the system were such that no current flowed in the middle wire, each cable would act just as a single sheathed cable. These proposals came from firms of the highest standing in the cable trade, and would show that there are many persons who have not yet fully grasped the importance of preventing waste currents. As I said before, the three conductors must be under exactly the same conditions, and within the same pipe or sheathing, to entirely do away with the difficulty, and a triple concentric armoured cable meets the case perfectly. But when a triple concentric cable is used as a distributing main, the question of service joints comes in, and it is not the easiest matter in the world to make a good branch joint on such a cable. Not only are the branches to be pieced in, but the cable itself must be left continuous. The low-tension cable we have adopted in Bolton is made by Messrs. Siemens Bros. and Co., Limited, and consists of three separately insulated conductors twisted up together into one cable, and then lead sheathed and iron armoured. The effect of the twisting is to make the three conductors have practically the same centre. The making of service joints is much simpler than with a triple concentric cable, as when the sheathings are cut through, each conductor becomes accessible, and can be treated as desired.

With reference to a three-wire system, it is often stated that when the load is equal on each side, no current flows in the middle wire But although this is often true, it is not necessarily so, as it altogether depends where on the particular main the lamps are taken off. Suppose we have a three-wire main going out from a station or supply centre, and that close to the station 100 lamps are taken off on one side. At 150 yards away let another 100 lamps be taken off, but from the other side. Then our meters in the station would show equal current in the two outer mains, and we might assume that none was flowing in the middle wire. But for 150 yards of its length it would be carrying a current equal to either of the outer cables. This of course is an exaggerated case, but it will show that it depends upon the positions, as well as upon the numbers of the lamps, how much current flows in the middle conductor.

A point of great interest in connection with an alternating-current scheme is, that although the low-pressure distributing network may be laid on the three-wire system, yet it is only necessary to have two-wire feeders. The transformers must be made with three terminals on the secondary coils, and the primary current will then adjust itself to the mean of the loads on the two sides of the secondary. If the transformers be designed so that there is only a 2 per cent. total variation in pressure from no load to full load, then the difference in voltage on the two sides of the system can never be more than 1 per cent. even in the almost impossible event of full load being on one side and none on the other. In such a case the primary would take a current equal to half full load. This is of great practical importance, as the station machinery and switchboards can be arranged for a simple two-wire system, while all the advantages of a three-wire distribution are retained.

At all the principal points of interconnection in the distributing network junction-boxes should be placed, so arranged that the various sections may be easily connected or disconnected for the purposes of testing, repairs, etc. Soldered joints would be here out of the question, so the cable ends should be sweated into thimbles, which may be clamped together, or to properly-arranged connecting bars, as desired. If the insulating material be other than rubber, then the boxes may be filled up with oil to keep out the damp. The oil could be pumped out in a few minutes when it was necessary to make a disconnection.

A very important point in connection with an underground system of mains is the question of insulation resistance. I am inclined to think that a great deal too

Digitized by Google

much is often made of shop tests on the cable, and far too little of tests when the cables are laid and all joints made. We may think because the cables give an insulation resistance of so many thousand megohms per mile after 24 hours immersion in water, that we are certain of an excellent system. Such tests and results are most excellent in their way, but what insulation resistance is obtained when the cables are laid? A badly insulated joint has a wonderful effect in producing bad results, and is practically equal to a faulty place in the cable. Therefore all joints should be most carefully watched while making, and a guarantee obtained from the contractor, rather of an insulation resistance when the cables are laid complete, than when individual coils are tested in a tank of water. Besides testing for insulation in the ordinary way, all cables should be tested for breaking down with a voltage at least twice the ordinary working pressure.

Conductors of bare copper should only be used for continuous currents of low tension, as if used for alternating currents it is practically impossible to lay them so as to avoid induction effects. They have been used by Crompton for continuous currents up to about 200 volts with considerable success, but on his system the conductors are tightly strained, and are supported on properly shaped insulators. In some cases bare strip has been laid in culverts, and carried upon porcelain bridge-pieces, which can only by courtesy be called insulators. Little or no attempt appears to have been made to prevent surface leakage on the supports, with the result that the insulation resistance of such mains is often a minus quantity. The liability of all such systems to stoppage from water flooding and the large sizes of the conduits required, are points against their use. Their only recommendation appears to be in the question of prime cost. A properly constructed and properly ventilated subway system under our streets would much simplify the question of laying electric mains. But the dangers arising from gas and water pipes bursting, to say nothing of the enormous cost, stand in the way of its adoption.

I trust these remarks may be of interest to the members of this society.

Various Systems of Underground Mains and Methods of Laying Same.

BY S. V. CLIREHUGH, A.M.I.C.E.

I feel that the subject of this paper needs no apology, as until quite recently the means by which electricity was to be conveyed to the consumer had not presented itself as one of the burning questions in the equipment of a central station. We have discussed in the technical papers and before scientific societies the question as to whether dynamos should be direct coupled or rope-driven. Columns have been written on the advantages or disadvantages of water-tube boilers as against Lancashire boilers, and vertical engines have been pitted against horizontal engines, but, as a rule, the question of the best system of mains has been left severely alone. Now, I am sure that any central-station engineer will bear me out in saying that the mains are one of the most important points of a central station, and on them depends to a very large extent the satisfactory working of the station. Everything else from boilers to dynamos is duplicated, but mains it is practically impossible to duplicate. There is no stand-by, hence the importance of selecting a system with the utmost care.

Let us consider what are the first things to be aimed at in any system of mains.

1. *Cheapness.*—This is always an important point to consider, as it is generally the non-technical public who find the money, and it is difficult to convince them that very often cheapness in this particular line is very false economy.

2. *Long Life.*—Very little actual experience is available as to the probable duration of any form of insulating material at present in use.

3. Facility for increasing the sectional area of copper without disturbing the surface of the ground.

4. Facility for fault-finding, repairing, inspection, jointing, etc.

Having detailed the various points which are considered desirable in a system of underground mains, we may now consider to what extent we can combine them in any one system, and what are the various materials at our disposal.

There are, broadly speaking, three systems to be considered: (1) insulated cables in conduits, (2) armoured cables, (3) bare copper in culverts. One of the oldest systems which was practised on anything like a large scale was that of laying cast-iron pipes 3in. to 4in. in diameter, into which were drawn insulated cables, boxes being built at first about every 80 yards merely for the purpose of drawing in the cables and making straight joints. This plan is in my opinion very suitable for a district in which it is difficult to ascertain the probable demand which is served with a high-tension alternating-current system—the *modus operandi* being as follows: a cable having a conductor of small sectional area, say, $^{7}/_{16}$S.W.G., is drawn into the pipe and the first consumers are supplied therefrom, transformers being fixed on each consumer's premises. When the demand becomes sufficiently great—that is to say when there are, say, 12 consumers within 100 yards—the high-tension services are then cut off in the boxes which are built as occasion arises. A transformer station is then built, and a low-tension main is drawn into the pipe. The high-tension feeder being left in is available for feeding this and more distant points. If it is likely to be necessary to draw in many separate cables, it is advisable to lay two pipes, as several cables laying in one pipe have a curious way of twisting themselves together, thus rendering it difficult to pull out any particular cable.

We now come to the question of the insulating material, which we are going to draw into the pipes. Insulated cables may at once be divided into two classes. One in which the dielectric is unaffected by the presence of moisture, the other in which the dielectric must be protected from moisture of all kinds by being hermetically sealed in a metallic envelope. The materials used to insulate the first class of cables are indiarubber, guttapercha, and bittite, and for cables of the second class, jute, hemp, cotton, and paper impregnated with oil, wax, or bituminous or resinous compounds. We will now consider cables of the first class. In connection with these the only insulating materials, as far as the author is aware, worthy of consideration are indiarubber and bittite—okonite, as far as the author knows, never having been made commercially in this country. Guttapercha, although probably the first insulating material used, is now used solely for telegraph and telephone purposes, and that now to a limited extent except in the case of submarine cables, where it still holds its own. The great objection to the use of guttapercha, except for submarine telegraph work, is that it softens at a very low temperature, and when exposed to the light and air becomes brittle and cracks, sometimes even crumbling away into powder. Cables insulated with vulcanised indiarubber stand no doubt from a scientific point of view at the top. We have now had considerable experience in the question of the life of indiarubber as an insulator I hardly know how many years, but I am sure Mr. Preece will be able to give us further data. I myself remember taking out some indiarubber cables which were laid in London for the London Electric Supply Corporation, and which had been in constant service many years, which showed not the slightest signs of deterioration, and I may mention that the only reason they were removed was to enable them to be made concentric; they were replaced, and are working to this day.

I should like to say a few words on the question of vulcanising indiarubber. As you are all probably aware, vulcanising has only been known about 30 years. I again must appeal to Mr. Preece. Prior to that time cables were insulated with pure rubber strip lapped spirally round the conductor, the overlapping parts of the strip being made to stick together by the use of naphtha, which is a solvent of indiarubber. This, of course, was most unsatisfactory, and caused the rubber to decompose very rapidly. I often wonder what will become of the mass of joints in house wiring in 20 years' time. Vulcanising, of course, went through various stages, with which I need not trouble you, before it reached its present one. The process is in itself very simple, but requires long practice and considerable skill before it can be satisfactorily carried out. It is as follows. A small quantity of sulphur is mixed with the rubber, [and the mixture is subjected to a

Digitized by Google

temperature of about 250deg. to 300deg. F., whilst keeping it under pressure. The difficulties presented by the process are the different times required by the different classes of rubber, varying from one to four hours, for the cure and the amount of sulphur to be used. By vulcanisation the sulphur combines chemically with the rubber, with the result that the decomposing agent is neutralised. In some places the difficulty offered by being unable to keep a vulcaniser is serious, as the men are highly paid, and on a small station there is not, of course, sufficient to keep even one fully occupied. In such cases it is sometimes necessary to use mechanical jointers—*i.e.*, cast-iron boxes which are placed over the joint, bolted together, and filled with a bituminous compound. This makes a thoroughly good job, but it is very difficult to break the joint should it for any reason become necessary. Another plan is to insulate the joints with pure rubber strip, and when there are sufficient number of them, say 20 to 30, ready to be cured, get the cable manufacturer to send a vulcaniser down for a week or so. Vulcanising, it will be seen, is a very delicate operation, the success of the joint being entirely dependent on the care taken by the jointer, and too much importance cannot be laid on the point of cleanliness. A rough test as to whether a joint is properly cured is to try and mark the rubber when cool with the thumb-nail; if it is just right it will yield to the thumb-nail, but leave no mark; if it leaves a mark it is under-cured, and if it feels hard it is probably over-cured. The only objections, therefore, to the use of cables insulated with indiarubber are practically its high price and the difficulties in jointing. I would specially warn engineers to be very chary of purchasing low-priced rubber cables, as it is almost impossible for anybody not an expert to tell whether the rubber is good or bad quality. Low prices in rubber cables generally means that a large amount of compound has taken the place of rubber.

We now come to the only other practical insulating material—viz., bittite—of which I regret to say I have had very little experience. Bittite, which is the material used by the Callender Company, is believed to be bitumen refined to purity and vulcanised. The conductor is covered with a solid sheath of this material put on in one operation under pressure, and is served with a tape and covered with an insulating compound and again taped, then braided with a hemp yarn and passed through a bath of hot asphalte compound. Joints in the cables are insulated by wrapping the conductor with bittite, which has been half vulcanised, up to the diameter of the original insulation, and then protecting it by a wrapping of compounded tapes. The joint is then heated by means of a lamp to make the wrappings solid and to complete vulcanisation. This system of jointing is very simple, and no particular training is required for the purpose. The Callender Company had at one time, I believe, difficulties which they have now got over, owing to the tendency of the conductor to decentralise, and I have also heard that the insulation sometimes stuck to the culvert, rendering it difficult to remove. However, my experience with them is not of recent date, and as I see a representative of the Callender Company here he will no doubt be able to correct any errors into which I have fallen. Callender's cables are used very largely, and I believe with great success, in this country for low tension, but up to the present not much for high tension.

You will see on the wall a table giving approximately the cost of a yard of main on the three-wire system, low tension, of the various classes of cables, etc., and also for concentric cables for high-tension systems; the item for excavating and making good of course varies enormously, both according to the town and the nature of the ground.

We now turn to cables of the second class—*i.e.*, the insulation of which is not in itself damp resisting, but which has to be protected by a metallic envelope, and on this I feel some difficulty in expressing myself lest I should appear prejudiced, as I was for two years engineer to the British Insulated Wire Company, whose speciality is fibrous insulation applied in the form of a paper. In describing one lead-covered fibrous cable you have described them all, as they all have the same faults and the same advantages apart from the question of excellence of manufacture, into

Approximate Cost of Laying a Yard of Main on the Three-Wire System—The outer conductors having a sectional area of four square inches, the middle conductor two square inches.

System.	Cost of conduit.	Cost of conductors.	Excavating and making good, including laying and jointing conduit.	Total.
		£ s. d.		£ s. d.
4 sq. in. C.I. pipes, with indiarubber insulated cables drawn in.	2s. 0d.	1 3 0	5s., including boxes at the rate of 12 per mile.	1 10 0

which it would be invidious to enter. I have said above that indiarubber as an insulator stands scientifically at the top, which is no doubt true, but it is expensive, and if you can get an article which will answer the purpose equally well at a lower price it is certainly advisable to use it. The question now presents itself as to whether a fibrous cable will answer equally well, and I say decidedly, yes, if you are prepared to treat it with sufficient care. Very frequently, however, fibrous cables get into the hands of jointers who have been given no special instructions, and they treat it as they have been accustomed to treat a cable insulated with indiarubber, with, of course, unsuccessful results. Fibrous cables are not so flexible as those insulated with indiarubber, but for nearly all practical purposes are quite flexible enough. The manufacture of lead-covered fibrous cables is fairly well known. I will not detain you long in describing it, merely saying that the fibrous material, be it in the form of yarn or paper, is laid spirally round the cable, pressure being applied to solidify the mass as much as possible to the required thickness; the cable is then thoroughly dried out at a temperature of about 250deg. F. for 30 or 40 hours to expel every possible trace of moisture, and it is then immersed in wax, resinous oils, or similar materials at a high temperature. From this tank, without any further contact with the air, it is passed through a lead-press and so hermetically sealed. The great danger in these cables to guard against is the possibility of the formation of "pinholes" during the process of lead covering. These are produced by a variety of causes, but probably the most troublesome one is produced by impurities in the lead. These "pinholes" are very difficult to perceive during manufacture, but they are generally found by testing after prolonged immersion under water. It is very important in buying this class of cable to find out what insulation resistance the manufacturer recommends and to see that all cables of the same class have approximately the same insulation resistance after one minute's electrification and 24 hours' immersion in water. The electrification being very marked in this form of cable, it is essential to see that this limit is adhered to. One word about the insulation resistance of these cables. I have found by experience that it is better not to insist upon too high an insulation resistance, but to insist on its being uniform. Cable manufacturers are a good deal

Digitized by Google

bothered by having high insulation resistance specified. It can be produced if desired, but, I believe, at the expense of the life of the cable caused by excessive drying out. The pressure test is a very useful one, and cables of this class should certainly be tested after immersion with at least double the pressure at which they are intended to work. The cables should again be tested for insulation resistance, and the result should be the same as before the pressure was applied.

We now come to the treatment of the cables after they are delivered in the streets, and we will assume they are to be drawn into cast-iron pipes. Cables which are to be thus treated should be either taped or braided outside the lead, preferably the latter, to prevent any roughness in the pipe scoring the cable. If the cable is a heavy one, some lubrication is often desirable, and for this purpose there is nothing better than soft soap. In a straight run with a moderate-sized cable, 80 to 100 yards may be drawn in in one length, great care being taken to avoid kinks or sharp bends. It will be noticed that the end of the cable is sealed up, and when this end is cut it must be resealed as soon as possible, as the insulation being very hygroscopic, the insulation resistance of the cable is quickly lowered if the end remain exposed too long to the atmosphere. A good temporary way of sealing the end of a cable is to lap it with dry cotton tape and plunge it into hot pitch. As regards jointing of these cables, you will see on the table samples of joints in various stages of manufacture which will illustrate the subject better than anything I can say. The only skilled labour necessary in making these joints is for wiping the joints, and an ordinary plumber will in the course of a few hours be thoroughly competent. Two holes are left in the lead sleeve, on to one of which a tube of about 12in. long is soldered and resinous oil is poured down the tube, the length of the column of oil causing sufficient pressure to enable the oil to thoroughly permeate the insulation of the joint. A straight joint in a concentric cable, say, $^{7}/_{16}$ S.W.G., should be completed in about one hour. When it is required to end a cable for any purpose a lead cup is soldered round the sheathing and filled with paraffin wax. The difficulties in connection with this class of cable are thus, it will be seen, largely overrated, and with due care it will serve every purpose that is served by rubber-insulated cables, the jointing being to my mind considerably easier. As regards the life of these cables, we are again without any actual experience to guide us, but I see no reason as long as the lead covering remains intact that any depreciation should take place. Through the courtesy of the Fowler-Waring Company and the British Insulated Wire Company, I am able to show you various samples of their manufacture. I think that, other things being equal, the paper insulation has an advantage from the fact of its cleanliness in jointing. The power of paper as a dielectric for resisting disruptive discharges is very high, and $\frac{1}{4}$in. radial thickness of insulation has been found sufficient to withstand a pressure of 20,000 volts, which, I believe, no other dielectric of this class would stand. No paper on this subject could pass without a word of reference to the mains invented by Mr. Ferranti. When Deptford was started and the idea of transmitting energy at a pressure of 10,000 volts was seriously entertained, no cable could be found which was likely to be able to withstand what was then considered an almost impossible pressure. Mr. Ferranti therefore invented his well-known main, a sample of which may be seen on the table, and it is noteworthy that after trying every conceivable form of dielectric he at last decided on paper as being most calculated to withstand the disruptive discharge. The first of these mains was laid when I was with the London Electric Supply Corporation some six years ago, and with the exception of damage caused by external injury they have been running very satisfactorily ever since. As these mains have now been quite superseded by the British Insulated Wire Company's manufacture which remove the principal difficulties in connection with their use, I need not trouble you with a description of their manufacture, which will be found in most text-books.

We have still one more cable under this class to discuss—viz., the Brooks oil insulation system. This system resembles the lead-covered fibrous cable system, as will be seen. The cables are sent out heavily braided, as will be seen from the samples; this braiding simply serves to keep the conductor from mechanical contact with the pipe. The iron pipes in which the jute-covered conductor and oil are contained are laid underground, and at the highest point in the pipe line a cast-iron tank is fixed, which serves as an oil reservoir and ensures the pipes being kept full of oil. The inlet to the boxes through which the cables pass are provided with glands, which thus allows the box to be emptied for testing purposes and making fresh connections. Those who have had anything to do with the heavy resinous oil used on this system will appreciate the difficulty of getting the oil out of the box and the horrible state of mess the jointer would be in. When the pipes and boxes have been laid and all joints made tight, the cables are drawn in. To prepare them for this stage, the braided cables are placed in a portable tank containing fluid insulating material, at a temperature of about 300deg. F., for a sufficient length of time to expel all moisture from the fibrous covering. They are then drawn into the iron pipes and oil is forced in to fill up all the spaces. This system might be suitable for feeders, but I should think it difficult to work on a system of distributing mains. I have, unfortunately, no figures as to the cost of this system. I have so far endeavoured to describe to you the various classes of cable which are suitable to be drawn into conduits and to point out the relative advantages and disadvantages of each, from which you will see that no hard or fast rule can be laid down, but each case must be governed a great deal by local circumstances.

Armoured cables may be dismissed very briefly—the principal object in their use is their supposed cheapness, which, however, is over-rated as will be seen from the table. They may be of service in outlying districts, and possibly in some cases for feeders, but there are many drawbacks to their use, one of the principal ones being the difficulty of fault-finding, as in any draw-in system whenever the fault is arrived at within, say, 20 yards, that length of cable can be drawn out and examined at leisure, whereas with an armoured cable you have to open many yards of ground before you actually arrive at it.

We now come to the last class of mains—namely, bare copper in conduits. Messrs. Crompton and Co. are the great exponents of this system, and you will see numerous samples indicating their system on the table. Much might be written on this class of mains, but as this paper is already of considerable length, it will suffice to describe one system—viz., the Crompton, as showing the principle—the other systems merely vary slightly in detail. The bare-wire system, it need hardly be said, is suitable only for low tension. The culvert consists of a concrete trench laid under the footway. The culverts are constructed of cement concrete, the wall in no case being less than 6in. thick and the bottom 4in. They are covered with York stone bedded in cement, and the culverts are rendered inside with cement, thus making it thoroughly waterproof. Boxes are built every 15 yards along the trenches, and these are the only places in which the cable is supported, so that the insulators are always open for inspection. The insulators are mounted on oak cross-bars (which are mounted on the concrete about 2in. off the bottom) and are made with a notch in the top on which the conductors rest. The culverts are connected, where possible, to the main drains. It might be thought that a film of moisture would collect on the insulators, thus giving rise to considerable leakage; the electrolytic action of the current, however, is said to be sufficient to resolve this moisture into its two component gases. We seem here to have a system which combines most of the desired qualities in a system of mains. However, this has its drawback, like all others. Firstly, in many of our great cities it is impossible to find room for this class of conduit, and then recourse is had to insulated cables. Secondly, a water-main bursting might possibly cause a stoppage of the supply; this, however, is not very likely to happen. Thirdly, gas is apt to accumulate in the conduits, giving rise to explosions. It is, however, less likely to get into a watertight conduit than into a system of iron pipes where there is no attempt made to keep out the water. Whether bare conductors are more likely to ignite the gas is a much-debated question. Only recently two of the technical papers had an article on the subject. One said it is

Digitized by Google

easy to see how the gas gets into the conduits, but what fires it? The other, however, wondered how the gas got in, but understood how once in, it was fired. Personally, I am inclined to believe that most explosions occur from lighted matches, candles, etc., being introduced into the boxes. As regards the life of this culvert system, it seems that we have at least got hold of materials which have stood the test of time—viz., oak, concrete, and copper.

I have dealt with this subject in a very sketchy manner, but time does not allow for more. To go into the details of each system would require a paper as long as this. I should have liked to mention some points connected with the use of concentric and triple concentric cables, and the effect of an alternating current in increasing the virtual resistance of the conductor, as also the question of dry core telephone cables, but unfortunately time does not permit. I trust that this paper may prove of interest to the members of the society.

THE FIRST THREE-PHASE TRANSMISSION PLANT IN THE UNITED STATES.

An example of a successful power-transmission plant operated on the three-phase system is that recently installed at Redlands, Cal., by the General Electric Company of New York, who have sent us the annexed description and illustrations. It is the first plant in the United States in which this system is employed. In few regions is water power more appreciated, and electrical power transmission more necessary, than in Southern California. For irrigation alone a water right there is better than most gold mines, for in spite of its marvellous sub-tropical climate artificial irrigation is a necessity almost everywhere. Without it much of the country would be barren and forbidding; with it, it becomes a fertile garden spot. Add to this indispensable irrigation the possibility of using the same water for the distribution of power over a region where coal is from 8dol. to 12dol. a ton, and the importance of electrical power transmission is evident enough. The first water power in Southern California to be utilised for the distribution of power, as well as light, is that situated at the mouth of Mill Creek Canon, nine miles from the city of Redlands, one of the most flourishing of the younger cities of the State.

Less than two years ago a few of the public-spirited citizens of Redlands saw the chance of utilising the fine Mill Creek power, and organised a company, chief among the members of which were Messrs. George N. Crafts, H. H. Sinclair, F. G. Feraud, and George S. Ellis, who have in other ways played an important part in the development of this city. The enterprise was rapidly pushed forward, and about nine months ago a contract was closed with the General Electric Company for the necessary apparatus. The hydraulic part of the installation is of more than usual interest. Mill Creek is a fine and unusually reliable stream that springs from the slopes of mountains San Bernardino and Gratback, the two loftiest of the Sierra Madre range. The main body of the stream and a convenient intake was found near the mouth of the canon, and by comparatively small deflecting dam of masonry, 40ft. long and headwards, it was possible to turn the water into a tunnel, 160ft. in length, cut through the rock, and thence into a heavy steel pipe line, which was brought down the stream a distance of 7,250ft., where was obtained a convenient site for a power-house. At the end of the tunnel is a sand-box, 75ft. long by 25ft. wide, to catch any sediment before the water can enter the pipe line. At this point the fall is in the neighbourhood of 353ft., giving exactly 160lb. pressure to the square inch in the receiver that terminates the pipe line, which can deliver 2,400 cubic feet of water per minute.

The power-house, shown in Fig. 1, is for the most part an excavation not far from the back of the creek, made in a singularly heavy rubble composed of large water-worn stone, very compact and dry. The roof is erected on very low side walls, and under the lean-to on the right is the wheel-pit, with receiver and Pelton wheels. The wheel shafts extend to iron shutters set in windows in a mass of rubble retaining wall that bounds the wheel-pit, into the dynamo-room, where they are directly coupled to several machines. This dynamo-room contains the following apparatus, as may be seen from Fig. 2, which gives an excellent view of its interior: two 50-kilowatt 10-pole three-phase generators, delivering current directly to the lines at 2,500 volts between lines, two D 10 exciters, each capable of energising the fields of both generators, and one 50-light 2,000-c.p. Thomson-Houston arc dynamo. With the stream at its lowest 800 h.p. is developed at the generators. Room is left and foundations are in place for a third three-phase generator and a second similar arc machine. The large generators run at 600 revolutions, give 6,000 alternations per minute, and have a rated output of 100 amperes at 2,500 volts. The general arrangement of the station was planned before the contract for the apparatus was let, and, in fact, before the character of the machinery was determined, substantially according to the designs of the late A. W. Becker, whose recent death was a substantial loss to the electrical interests of the Pacific Coast. To each of these large machines just mentioned a Pelton wheel is directly coupled, the three-phase generators being supplied with 200-h.p. double wheels, each operated by a double nozzle. The regulation of the hydraulic power is by the ordinary differential nozzle operated by Pelton differential governors, driven from one of the exciter shafts. A second small differential governor, driven from the other exciter shaft, steadies the action of the first by regulating the exciter wheels. The water having done its work is discharged into a ditch and utilised for irrigation purposes. On the side of the dynamo-room, opposite the dynamos, are located the switchboards. The chief interest of these lies in the three-phase switchboard for the two big generators. This is elaborately devised to meet every condition or combination that it might be desired to make with the two machines and the two circuits that run from the power-house. Either machine can be thrown on either circuit, and both machines in parallel on either or both circuits. At present the parallel connection is chiefly used in shifting over the load to one in perfect continuity of service. A six-ton travelling crane permits ready handling of any of the machinery. The interior of the station is a model of its kind. Particularly to be noted are the excellent foundations which are carried deep down into the solid rubble, and are built up with a liberal supply of cement, sharp gravel, and small stones. In the upper portion of the foundation equal parts of cement and gravel are used, and the top layer is of pure cement. To this smooth surface is bolted a framework of oak about 3in. thick. On this rests the dynamo, which is secured to it by bolts firmly screwed up and bedded in sulphur. The result of this careful foundation and excellent alignment of shafts is that the large generators run without even a tremor at the bearings.

The whole fitting of the station is admirable, and the same care is extended to the little house of the engineer (seen in Fig. 1), which is lighted from one of the exciters, and is to be furnished this winter with electrical heating and cooking apparatus. From the power-house are run two three-phase circuits, each composed of three 00 B. & S. wires. One of these runs to the company's office, at Redlands, a distance of 7½ miles, and from thence is distributed over the city for lighting and power purposes. On a substantially built pole line the other extends to Mentone, 4½ miles, where is located the artificial ice plant of the Union Ice Company. In this plant is installed a self-starting 150-kilowatt triphase 750-revolution 6,000-alternation synchronous motor, belted through the medium of a countershaft to two large compressors for the ammonia, a circulating pump for the compressor jackets, a force pump to supply water for the ice, and a small elevator for handling the ice. In order to ascertain the point of synchronism, a Thomson acoustic synchroniser is employed, and gives unqualified success. The ice plant is of the so-called "Pipe" type, and the freezing-room and condensers contain nearly 20 miles of ¾in. iron pipe, in testing which the motor was stopped and started at short intervals for several weeks. The operation of the ice plant is continuous, the load being on the motor 24 hours a day, and, barring accidents, 365 days a year. The motor plant at this point is likely soon to be increased to keep up with

Digitized by Google

an increase in the plant. From the main Redlands circuit a number of lines are taken off the ice plant, and also for the neighbouring town of Mentone. There are now in operation 30 arc lamps, besides over 1,000 16-c.p. incandescent lamps distributed over three lengths of legs of the circuit. A number of small induction motors

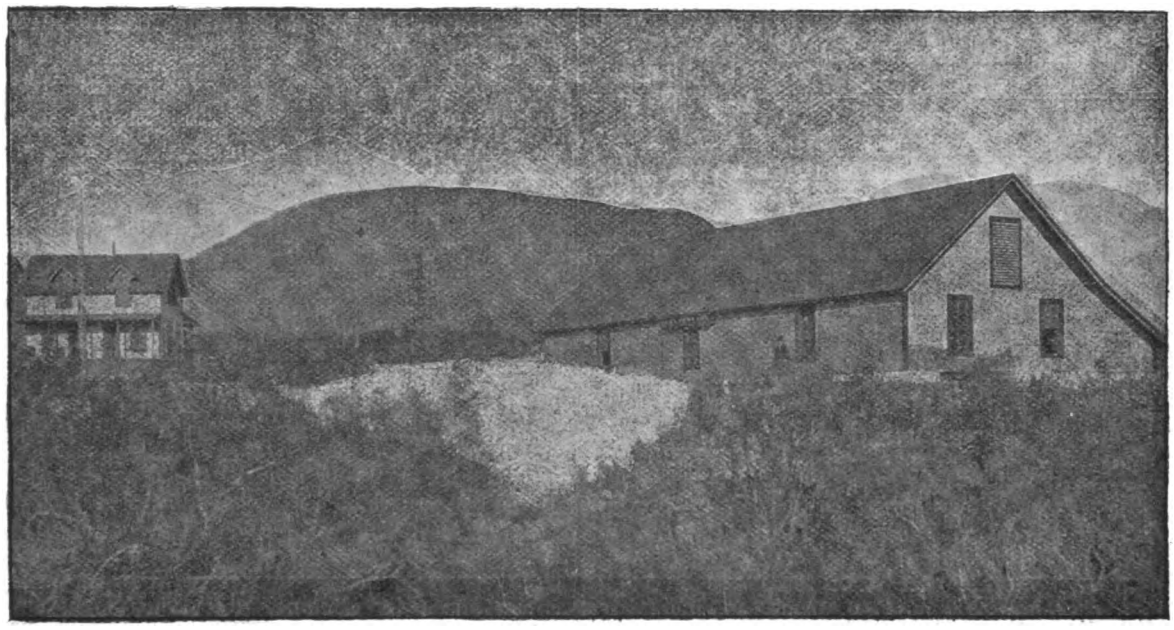

FIG. 1.—The Power House at Redlands.

without commutators or collecting rings are to be installed shortly, to meet the demand already created by the success of the plant. The transformers are very similar to the ordinary General Electric type T transformer, except that they are designed for 50 cycles per second, and to reduce the pressure from 2,200 to 110 volts. So far as possible, rather large transformers are used with comparatively long secondaries. These are used only directly at the point where light and power are delivered.

No trouble whatever has been experienced from any unbalancing of the lighting lines. In fact, shortly after the plant was started, the largest single block of lighting in the city, wired for three circuits, had these circuits worked for several nights on two legs of the triphase generators, pending the setting up of the third transformer, and although the lights from these two legs were set in adjacent rooms, where both would be seen at once, not the slightest trouble from unbalancing was evident. The first generator reached Redlands on September 1, and on September 7 incandescent lamps were turned on in Redlands, where arc lamps had been previously working since the latter part of July. On September 13, the motor at the ice plant went into commercial operation. The whole plant has been running steadily, and doing good service ever since.

The plant has now been in thoroughly successful operation, and the General Electric system and apparatus has given entire satisfaction, for several months; and with the progressive and business-like management of the company bids fair to be not only a succesful power transmission, but an eminently satisfactory investment. Its operation has been singularly free from difficulties of every kind, and it appears to be a thorough demonstration of the adaptability of the General Electric Company's three-phase system to the work of transmission for both power and lighting.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. Biggs, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"The Electrical Engineer" *can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—*

	3 months	6 months	12 months
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements should be made payable to C. H. W. Biggs, *139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."*

BOUND VOLUMES.

Vol. XII. of new series of "The Electrical Engineer" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

THE GUILEFUL PATENTEE.—II.

Our correspondent Mr. Fitz-Gerald is probably correct in his conclusion that our article of last week was too sweeping in its condemnation. He agrees with us, however, in anathematising a certain class of inventors and patentees, and we think this class includes by far the greater number of patentees. There are exceptional cases, and exceptional cases need exceptional treatment. It is true that the company promoter has, to the detriment of the patentee, lined his own pockets with cash while the originator has had to be satisfied with a small sum, hardly enough perhaps to keep him from starvation for a month or two, with additional promises in the shape of dividends to come on shares. Too often the whole scheme has fallen through as soon as the promoter obtains satisfaction, or the value of the shares has been reduced to nil by the issue of preference shares and debentures. We agree to all this. In our eyes the company promoter is a kind of necessary evil in civilised states—an evil which has to be tolerated and kept under as much as possible, inasmuch as the tendency of the evil is to grow worse and worse, till it becomes a method of gigantic swindling. The company promoter is worth his fair pay, but when what he takes goes beyond this, nothing good can be said of him. If it becomes the duty of a technical journal to discuss these questions, it is only because the avaricious greed of the promoters connected with the technical applications has been so disgraceful that further danger must be averted by plain speaking. Spencer Balfour's name is in the mouths of everyone, and he is looked upon as a pariah even among promoters; but we think this general feeling is due to deliberate attempts on the part of folks as bad, or worse, than himself to paint him blacker than he really is. Bad as we know this man to be, we imagine the revelations to come will show that others who are now bespattered by flatterers and sycophants will be shown to be worse. The crust of the investigation into trust companies has only been broken. When we get further and know who really started these affairs—who, for example, was the biggest holder of founders' shares in such places as Winchester House—and pursue the ramification of their workings, there will be more astonishment in the City than has been seen for many a year. We are credibly informed that the evidence is almost complete, and may descend like a thunderbolt at any minute. Probably, however, Mr. Spencer Balfour holds some of the threads wanted, and his much-wished-for arrival in this country will be the signal for some startling revelations. We only refer to this matter because, among other things, Mr. Spencer Balfour was mixed up with some electrical companies, and in one case especially very large sums went among the promoters. But what has all this to do with patentees? Merely to show that some promoters are on a par with some patentees. We must, in the face of Mr. Fitz-Gerald's letter, except that very small class which unfortunately suffers nothing but hardship, both on the side of the patentee and the promoter. As a

Digitized by Google

rule, the bigger the swindle and the bigger the liar, the easier to obtain money; while those desirous of real work and real improvement find it extremely difficult, nay, often impossible, to obtain their modest and moderate requirements.

We cannot, however, even while admitting the hardship to the honest, earnest, masterly patentee, budge from the broad conclusions of our article. It is only in exceptional cases that the patentee cannot get his supposed improvement carefully considered by the management of the large manufacturing companies. It is in the interest of the management to obtain improvements. One thing, however, is far too often forgotten by the patentee who is outside a manufacturing concern. Let us take for a specific example the would-be improver of a dynamo not engaged in a factory. Few of those who fill the files of the Patent Office know and understand the constant experiment that goes on in the factory, the constant thought in the drawing office to the perfection of details; and dozens, scores, nay, hundreds, of the suggested improvements are known to the practical man to be impossible and valueless. The patentee in submitting his scheme is told so, but he doesn't believe one word that is told him, and immediately sets out to go the round to induce someone to advance money to give his patent a trial. Study the Patent Office specifications and see how few contain even a germ of improvement. Hundreds are filed by men who have only the most superficial knowledge of the subject, and are for things that have years ago been tried and found wanting. It would be interesting to know how many patented improvements have been offered to and rejected by, say, Messrs. Sellon and Raworth, Mr. Crompton, Messrs. Johnson and Phillips, Messrs. Siemens, and other of our large firms. If such statistics could be given, we think our contention would be proved to the hilt—that the majority of patents are utterly valueless, that the majority would be considered by such firms as we have named, and that the residuum of valuable inventions not taken up by such firms is small. The hardships undergone by this small residuum is, nevertheless, a real hardship.

STEAM-ENGINES FOR CENTRAL-STATION WORK.

A pudding may be considered highly satisfactory when jaded appetites have made a clean sweep of it, and this well-known statement may serve as foundation for generalising from results in every case. In a very short while, for instance, electrical engineers will probably have obtained such exhaustive and complete results, or working experience, as may enable conclusions to be drawn respecting the most suitable type of prime mover or steam-engine for central-station work: and those who intend to erect and equip large electric lighting plants—whether privately or on behalf of municipalities—during the next few years, cannot watch too carefully the working results obtained from the stations already at work, making due allowance for the varying cost of fuel, etc., in different localities.

At the present time, indeed, it would almost appear as though the most suitable type of steam-motor were already justifying its adoption in comparison with any other of the numerous arrangements experimented with. At any rate, there is a remarkable coincidence between low works cost and the employment of high-speed compounded steam-engines of the inverted vertical form. We do not of course assume any casual connection whatever between these two circumstances: their concurrence in so many cases may be due to chance, and chance only; but if the continued adoption of such motors should always result in a low working cost, there would be strong justification for examining into the matter with a view to prove the connection or not. There are naturally several complicating conditions, one of which—the relative cost of fuel—we have already mentioned. Besides this, the system adopted, alternating or continuous current, the methods of distribution, and the character of supply area, etc., must all have undoubted influence upon works cost per unit. Separating these, however, as far as possible, it is, we think, well worth while to look into the question of prime movers in order to find the best and most economical type for long service. It may not be out of place to suggest a comparison between the high-speed vertical engine and the slow-running horizontal type with Corliss or other quick-acting valve gear. Seeing that the average load factor of electric light stations is at present so extremely low, the latter type of engine has many disadvantages, not the least of which is its comparative inefficiency when running much under load. Their small range of cut-off is largely responsible for this. Probably it may be found that a combination of engines will best serve the purposes of an electric supply station: high-speed vertical engines—compounded, of course—for the light loads, and heavy, slow-running horizontal motors for use at times of full load.

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

INVENTORS AND PATENTEES.

SIR,—Although there is one class of inventor and patentee—a man ignorant and impudent, who works in the dark and invariably preys upon ignorant members of the public—who should be extirpated by every possible means, I think that the general tone of your leader on "The Guileful Patentee" is unfair and one-sided. If this be so, a very large section indeed of your subscribers and readers—those who are more or less interested, from various points of view, in invention and patents—have cause to complain. But especially the honest, enthusiastic, and laborious, albeit "impecunious," originator in the domain of applied science may consider himself aggrieved; for he can have no doubt as to your grim intent to starve him out of existence, if that can be done by writing him down. This would be hard upon inventors, for, to parody a passage in your leader, many have been long years at work, and, by study, intelligence, and industry, have embodied such valuable ideas in a patent or patents that they might fairly expect a competency to result therefrom.

The inventor is usually a patentee, because the patent laws afford him almost the only opportunity he usually

Digitized by Google

has of making any profit out of his inventions—*i.e.*, of turning to account his training, time, and labour. And who can estimate the benefits conferred upon the community by the inventor—thinking, experimenting, labouring with brain and hand, by day and by night, and often, alas! starving, whilst the astute man of business reaps the benefit of the initiative taken by men of a higher order of intelligence working for all humanity. Paccinotti, Goodyear, Bessemer, Gramme, Faure, Gaulard, S. Varley, and many who have fallen unknown—where should we be without them?

In regard to dupes, the originating inventor seems often to be regarded as fair prey for anyone having the "gift of the gab" and wit enough to pirate or over-reach. Have you never heard of an inventor parting with his patents in consideration of a large sum—in shares afterwards rendered valueless by the issue of "preference shares"? Have you never heard of an inventor being fleeced, not only of his patents, but even of the credit attached to his inventions? If not, you can hardly realise how much there is to be said on that side of the question you have left out of consideration. There is plenty of work also in running down sham inventions and non-valid patents—too often turned to profitable account—whilst inventions of real merit are neglected.—Yours, etc.,

DESMOND G. FITZ-GERALD.

TESTING THE HYSTERESIS IN IRON.

SIR,—In your issue of March 3 you gave Mr. Kapp's very interesting method of, in workshop practice, measuring the hysteresis in the iron plates used for transformers and armatures. As was pointed out, what is wanted is not so much absolute measures of the hysteresis as relative ones, so that the manufacturer can compare different samples of iron and can ensure that he is getting iron of uniform quality. We have for some time past used a very simple method of comparing different samples of iron depending on the rise of temperature of the sample when subjected to an alternating magnetic field.

Two solenoids on wood frames, and identical in every respect, are coupled in series on an alternating circuit. Into each of these a core is put consisting of a definite weight of iron plates, insulated from one another with paper, and having in the centre a piece of wood with a slot for a thermometer. One of these cores is prepared of plates which are considered standard, and the other of the plates to be tested. Readings of the thermometers are taken at intervals, and the one which shows least rise of temperature is considered the best iron. The induction in the iron can be varied both by varying the E.M.F. on the coils and by varying the weight and number of plates in the cores. The whole apparatus is so simple that it can be worked by an intelligent apprentice.

We may say that we have found no advantage to be gained in annealing the plates as obtained from the makers, but unless insulated from one another by some medium such as paper, the loss is largely increased.—Yours, etc.,

C. A. PARSONS AND CO.

Heaton Works, Newcastle-on-Tyne, March 12, 1894.

RUNNING IN PARALLEL.

SIR,—I think Mr. Metzger's letter *re* "Running Alternators in Parallel" calls for one or two remarks.

If you are running alternators in parallel you should have a sufficient number in, so that in the event of anything happening to one the other machines will not be seriously overloaded. But should this be the case, you could then switch off a circuit till another machine was put in, although I think it is far better to run the whole system at a slightly lower voltage than to have any one part of it totally extinguished.

Mr. Metzger's circuits must be very nicely arranged so that he can load each machine up to its full capacity, and unless he can do so it is better to run, say, six machines in parallel at 80 per cent. of their full capacity than to have some running about 50 per cent. and some 100 per cent.; and, again, you can pull out your machines as the load goes off, whereas in the other way you have to wait till each machine has no more than half its load before you can transfer the circuit on to another machine, and unless the machines are put in parallel to do it you cause a great fluctuation in the light.

Surely, Mr. Metzger, citing the case of the Bankside breakdown, must know better than to think that 75,000 lights are run on one pair of mains.

The Brush Company have devised an apparatus for cutting out an alternator should the current run back on it from any cause whatever.

A. G. C.

London, March 10, 1894.

REVIEWS.

The Engineer's Year-Book of Engineering Formulæ, Rules, Tables, Data, and Memoranda in Civil, Mechanical, Electrical, Marine, and Mine Engineering. By H R. KEMPE, A.M.I.C.E, M.I.E.E. First year of publication. Crosby Lockwood and Son.

This is a book somewhat after the style of Molesworth, which, owing to the continuous changes in many of the data, it is proposed to correct and publish annually. It has been impossible to examine very closely into the numerous figures and formulæ contained in a closely-printed book of nearly 600 pages, but the position and ability of the editor make it certain that the greatest care and attention have been given to ensure accuracy. There is one feature of this book to which we decidedly object—not connected with the editor, but with the publishers. Men do not buy books of this kind to be bothered with advertisement pages inserted in the text. Advertisers will gain little or no benefit, because busy men will simply tear out these inserted advertisement pages, leaving those legitimately placed at the beginning and end of the letterpress. The electrical engineer's duties are inextricably connected with mechanical engineering so that, as a rule, a pocket or year book devoted solely to electrical figures and formulæ is not what he wants. But his requirements are of a more general kind; perhaps some will think not quite so wide as this year-book, though we think the wider information is on the right side. We contend, then, that electrical engineers will find this work useful, even though it has but a comparatively small section devoted directly to electricity. A book of this kind needs a very exhaustive examination before it can be said to be complete, and this we have not yet been able to give it; but so far as a brief examination is concerned, we find the information such as is wanted, it is given in a clear and concise form, the diagrams and figures are correct and up to date, while the index, were it not for these bothering interpolated advertisements, is very good.

A Text-Book on Electromagnetism and the Construction of Dynamos. Vol. I. By Prof. D. C. JACKSON, of Wisconsin, New York, and London. Macmillan and Co. Price 9s.

We must confess that the price of this book seems excessive, especially when it is considered that the author admits: "No special originality is claimed for the matter presented except in certain details; but it is hoped that the logical arrangement, and the omission of all unnecessary details, will make the book of so convenient a form as to lead to its general endorsement as a satisfactory text and reference book." We may endorse the verdict that this is a satisfactory text-book for college classes, while saying that the cost is too great. It is possible to pay too much for a good thing, and when we consider again that this volume does not touch upon alternate-current machinery nor series arc lighting machinery, but that these subjects are reserved for a second volume, we think our protest justified. The authorities consulted by the author are duly acknowledged. There is no doubt but that the author has carefully examined and condensed into this treatise the very latest information, and that for the special purpose for which the book is designed he has produced an excellent work. It is, of course, more mathematical than physical. Many of the chapters are exceedingly clear, and must render the task of the student much lighter than when he has to seek for conclusions among the original memoirs.

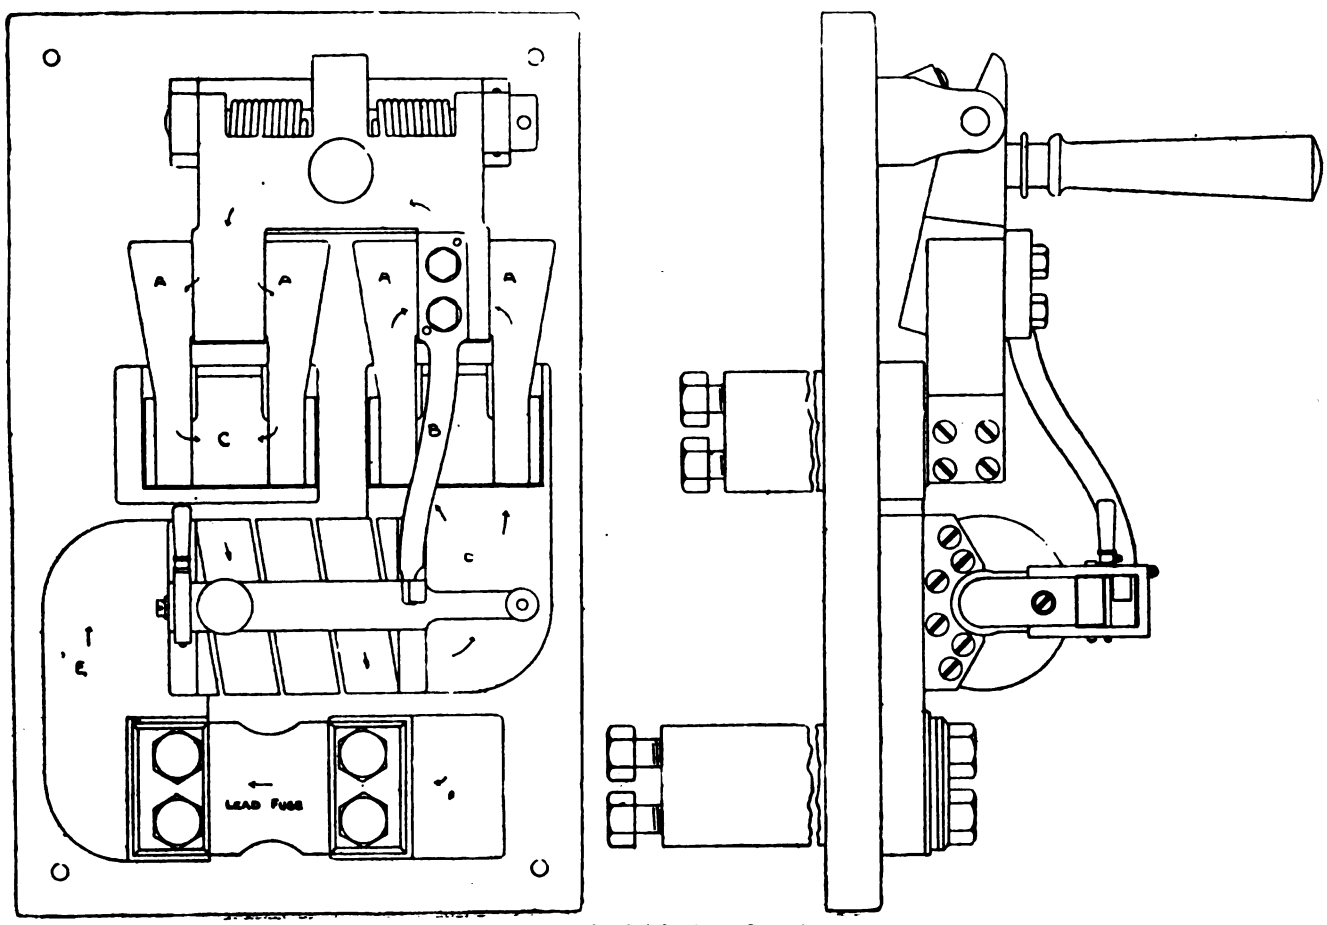
AUTOMATIC CUT-OUT FOR LARGE CURRENTS.

In a recent issue (see the *Electrical Engineer*, 2nd inst., page 258) we described and illustrated a large new main switchboard now in course of erection by Messrs. Siemens Bros. and Co., Limited, at the Carnaby-street station, belonging to the St. James and Pall Mall Electric Supply Company, Limited. On this board are fixed several massive automatic cut-outs for large currents, one being provided for each machine feeding into the omnibus bars. The details of these given in the article referred to were, however, not perhaps sufficiently minute to enable our readers to clearly understand their design and construction. We therefore append illustrations showing in outline form the front and side views of the automatic cut-out thus employed to carry 1,500 amperes as a maximum. The course of the current through this appliance is shown in the front view by arrows. It enters at F, from massive terminals at the back, taking two cable leads. From the brass block, F, it passes through a lead fuse to another block, E, connected to one end of a heavy copper solenoid, round which the current travels to another block, D. On the latter are mounted the laminated spring contacts, A A, between which the contact-piece, with arm, B, is pressed down. The current then passes through the heavy swinging switch block at the top of the appliance (pivoted as shown, and provided with powerful coiled springs tending to force it outwards, so as to break contact), down the other arm, through a similar contact-piece, to a second set of laminated spring contacts, and thence to the front block, C, with massive out-going terminals at the back. The solenoid is provided with an armature and a catch, by means of which the lower end of projecting bar, B, may be held so as to retain the switch blocks in contact, in the usual way. Strong handles are fixed in the main switch block and armature frame for the purpose of replacing these by hand after being thrown out. There is also a pin in the framework at one end of the solenoid by which the armature may be fixed in position if it is desired at any time to work non-automatically. A stop block is provided at the top of the instrument, with indiarubber cone, to limit the action of springs when throwing forward the switch block and arm, B.



Automatic Cut-Out for Large Currents.

ON THE DESIGN OF ELECTROMAGNETS FOR SPECIFIC DUTY.—II.*

BY E. R. CARICHOFF.

Electromagnets may be designed, as was shown in a previous article, with a certain length of air-gap, which, if multiplied by the pull between the armature and the poles separated by this air-gap, gives a maximum. The length of this air-gap is different for different values of the magnetic induction, and may readily be determined.

For example. Suppose the magnet to be made of cast steel, the $\mathfrak{B}$ $\mathfrak{H}$ curve of which is furnished by the Syracuse Steel Foundry Company, and plotted in Fig. 1 as curve 1.

Draw a tangent to any point of curve 1, and parallel to it draw a line through the origin, then the point where this parallel cuts the horizontal line drawn through the point of tangency is one point of curve 2, the abscissæ of which represent the magnetomotive forces for different values of the induction in the variable air-gap above defined divided by the length of the magnetic circuit in the steel.

The abscissæ of curve 3 represent the length of these variable air-gaps in ten-thousandths of a centimetre, corresponding to different values of the induction, $\mathfrak{B}$; also for each centimetre length of the magnetic circuit in the steel. The successive points of this curve are determined from those of curve 2 by dividing each abscissa by its corresponding ordinate.

Curve 4 is plotted from a table that is given in S. P. Thompson's book on "Magnets," and was calculated from Maxwell's formula,

$$P = \frac{\mathfrak{B}^2 A}{8\pi},$$

using such units that the abscissæ are pounds per square inch of polar area instead of dynes per square centimetre.

* From the *Electrical World* (New York).

Digitized by Google

Denote the abscissæ of curve 4 by P in pounds, those of curve 3 by L in ·0001cm., the length of the magnetic circuit in the steel by l in centimetres, and the polar area by A in square inches. Then work, being defined in this case as initial pull times travel, is expressed by

$$W = P \times L \times l \times A.$$

Assume W to be 10 centimetre-pounds, then

$$A\,l = \frac{10}{PL},$$

and the values of $\frac{10}{PL}$, corresponding to the successive ordinates, $\mathfrak{B}$, give the abscissæ of curve 5. $A\,l$ is a volume in which l is in centimetres and A in square inches, and this is seen to be proportional to the work, as above defined, which the magnet is capable of doing.

To illustrate the use of curve 5, suppose it is required to move a lever arm a distance of one centimetre against a pull of 100 pounds, W = 100 centimetre-pounds.

Assume $\mathfrak{B}$ = 13,500. We see that for this value of $\mathfrak{B}$ and for W = 10 centimetre-pounds, $A\,l$ = 18·5; for W = 100 centimetre-pounds, $A\,l$ = 185. Of course, we may give to l or A any value we please; but as the magnetomotive force, $\mathfrak{F}$, varies directly with l, there is economy in making A large and l small—just long enough, in fact, to permit the necessary winding.

As an example, try l at 20 centimetres and A at 9¼ square inches. The total magnetomotive force becomes

$$\mathfrak{F} = 20\,(18{\cdot}3 + 70) = 1{,}766,$$

and the ampere-turns are about eight-tenths of this, or 1,420. If these dimensions do not afford sufficient space for proper winding it will be necessary to increase l.

The total length of the air-gap will be

$$L\,l \text{ or } {\cdot}00515 \times 20 = {\cdot}103 \text{ centimetre.}$$

If the air-gap is divided into two variable parts, it is evident that the movement of the armature can be only one-half of the total air-gap, and a 20 to 1 lever will be required to move the 100lb. over a distance of one centimetre, as required. But if one air-gap only is variable, the other being an almost negligible constant, a 10 to 1 lever will suffice.

A form of magnet sketched in Fig. 2 will afford one constant and one variable air-gap. The constant air-gap at the neck of the magnet may be made very short and of large area. The upper cylinder is guided by the brass ring at the neck and by the brass rod sliding in the lower cylinder.

The accompanying table has been arranged partly from the curves above and partly from calculations on the slide rule. It shows some very interesting relations.

If it is desired to move the lever arm against the increasing force of a spring, the magnet may be made to balance this force at two points of its travel by selecting the induction to give the required pull at these two points.

15,500	138·8	·0146	2 02	4·93	260	3·78

Much of this article and of the one preceding has been presented in the form of suggestions, which may be elaborated to suit individual cases.

Digitized by Google

The main facts that seemed to the writer as useful are that there is a certain length of air-gap for any given magnet of uniform cross-section where the pull between armature and poles is lessened if the polar area is either increased or diminished, and that the pull under these conditions, multiplied by the length of this air-gap, is greater than the pull with any other air-gap multiplied by the length of the latter.

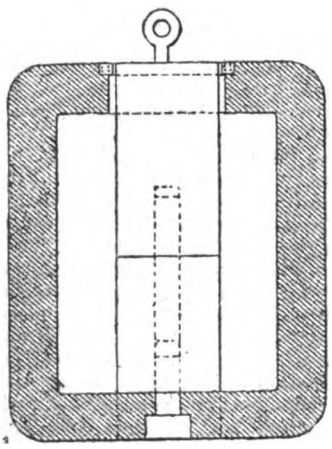

FIG. 2.

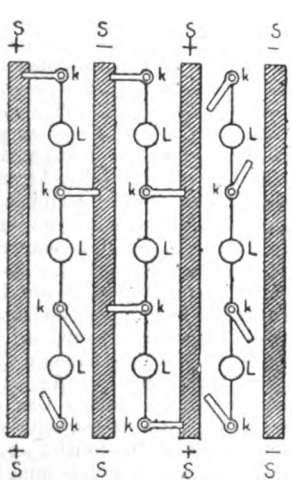
The use of different systems of units may seem objectionable to some, but when accustomed to the calculation of magnets in pounds per square inch the term grows to mean something more definite to the average worker than dynes per square centimetre. It is a simple matter to change the relation, and those who prefer the use of the same dimensions throughout may pass a pleasant hour in drawing curves to suit the units they prefer.

HEIMS'S LAMP RHEOSTAT.

The use of lamps as a means of regulation, and even of testing, is attended with many advantages; a notable feature being freedom from induction. Herr Heim has arranged a lamp rheostat which combines the following qualities: (1) a single lamp, or a series of incandescent lamps can be subjected to widely varying pressures; (2) the resistance is variable, and may be graduated to any desired extent.

The lamps are placed in a certain number of rows, each row being in series. In the figure three such rows are shown with three lamps, L, in each. At both sides of each row are two bars, S S, and by means of the switches, K, which make contact between the lamps and bars, a great number of combinations may be made. When a switch



forms a right angle with the bars it is in connection with them. When the angle is from 30deg. to 60deg. it does not make contact. To arrange the lamps in parallel as in the illustration, all the bars are connected alternatively with the positive and negative poles of the source of current, and the switches placed on the bars left and right. The middle row is joined up in this manner. Each of the switches carries a current double that necessary, and supplies the lamps on each side of it. In this way all the lamps are in parallel, and any lamp may be cut out by a simple movement of a switch.

If the pressure is found to be excessive, the lamps can be grouped in series parallel. The two switches at the ends of each of the two groups may be placed on the bars as long as the intermediate handles are not in contact with either of them. The pressure will then be found greatly in excess of that required for one lamp, but if it does not exceed double the proper value, and is between the one and the other, the groups of two lamps in series may be inserted in parallel. In the same way, groups of three, four, or more lamps may be inserted in parallel until all the rows of lamps in parallel are taken in. In case, however, the pressure in any bar is still too great, more lamps can be grouped in series than are contained in one row. In fact, there is hardly any end to the various ways in which the lamps can be grouped in single parallel, in series, or multiple series, but we doubt very much if the apparatus will come into extensive practical use.

ELKHART TRANSFORMER.

The Elkhart transformer is of the tooth type, and one of its principal claims for attention is that the coil may be removed, inspected, and replaced in a very short space of

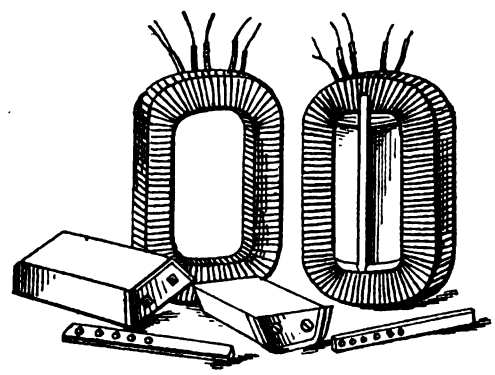


FIG. 1,

time without destroying the integrity of the laminations of the iron. All the coils are interchangeable, and by having an extra coil at hand repairs may be made in an extremely short time. Fig. 1 shows the parts of the transformer,

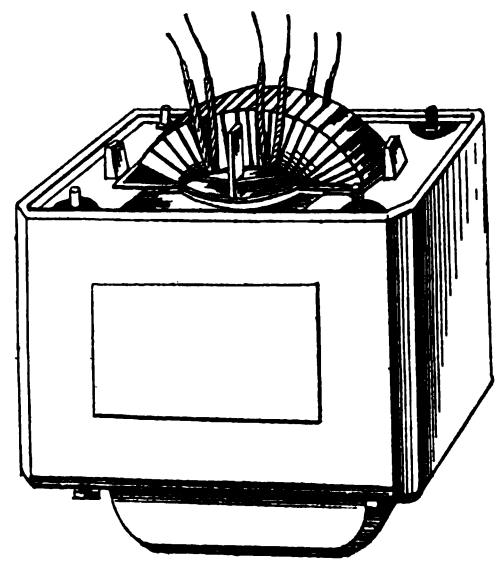

FIG. 2.

and Fig. 2 the appearance of the box ready for service. In the mechanical construction of the converter the outer magnetic circuit is unbroken, the laminæ are placed in the case under hydraulic pressure, thus making them practically noiseless. The core-pieces when placed in position occupy the V-shape cut in the outer laminæ, and by means of the wedges the magnetic resistance is reduced to a

Digitized by Google

minimum by practically making each lamination one piece of iron. In the coil construction a compound having high insulating qualities is used, rendering the complete coil practically indestructible and impervious to moisture, the whole constituting a solid mass of wire and insulating compound.

THE UTILISATION OF SMALL WATERFALLS.

M. F. Chédeville, in the columns of a French contemporary, makes some remarks on this subject in reference to a paper read by M. Hillairet before the Société des Electriciens on the utilisation of waterfalls for the transmission of power. He suggests that the water itself should be made to fulfil the functions of an accumulator, and that the ground in the vicinity of the fall would probably be of no great value, and might, in consequence, be utilised for building a reservoir. Variations of water supply would thus be got rid of and a greater output obtained. If, moreover, the ground occupied by the reservoir is sloping, a considerable increase in the height of fall may be obtained, especially if several partial falls have been collected into one. Assuming that each lamp is alight, on the average, for five hours per day—which is certainly too much—then by using the reservoir one would get 15 times more power from the fall than if it were used in the ordinary way only during the hours of lighting, and certainly three times more than with the use of accumulators without the reservoir. There would also be a great advantage in being able to obtain a considerable amount of power on special occasions, without the expense and depreciation of a battery. If high-tension alternating currents be used, and transmitted to neighbouring towns with sub-stations, one is more at liberty to choose an advantageous spot for the reservoir. This system will necessitate the use of larger machines, on account of the increased power of the fall. The machines will be more efficient, and working expenses reduced, on account of the shorter hours of working. As an example of the advantages to be derived from the above system, the author describes one of M. Claude's installations. The necessary power is supplied from one of the tributaries of the River Marne, where, without much cost, a 10-metre fall can be obtained. The village to which it is desired to transmit power is at a distance of 1·5 kilometres from the fall. The surplus power might be utilised by several small villages in the vicinity. The flow was carefully measured several times during a year which included two exceptionally dry periods. The results of these observations are plotted in a curve. The limits of flow were found to vary from 1,300 to 35 litres per second. The average flow was 225 litres per second. During a period of frost it fell to 100 litres per second. If the fall were utilised in its natural condition, one could depend only on 80 litres per second in winter, and with no regularity. Assuming an output of 75 per cent. for the turbine, 80 per cent. for the dynamo, and 90 per cent. for the line, there would be 5·76 h.p. available at the terminals of the lamps, sufficient for 75 16-c.p. lamps. Now, if a battery of accumulators were employed, and six hours be the maximum duration of lighting, the fall would be utilised four times longer, and the available power becomes 16 h.p. during six hours, or sufficient for 240 16-c.p. lamps. The stream under consideration flows in a confined valley about 100 to 200 metres wide; at one point there is a waterfall of about five metres in height, and one kilometre away another fall, with a slope about six metres between them. The valley at the second fall is only about 50 metres wide, thus being eminently adapted for the construction of a dam. The reservoir would occupy an area of 15 hectares, and if we assume a depth of 12 metres, the contents would amount to 1,800,000 cubic metres. Assuming a mean fall of 16 metres, and allowing 75 per cent. efficiency for turbines, 90 per cent. for dynamo, 90 per cent. for line and transformers, 156 h.p. would be available at the lamp terminals, and would therefore be capable of lighting more than 2,300 16-c.p. lamps during six hours in winter and two hours in summer. It is thus possible to obtain 25 times more power than from the fall in its natural condition, and seven times more than with the use of accumulators.

A PLEA FOR SERIES ELECTRIC TRACTION.

BY NELSON W. PERRY, E.M.

During the few years prior to 1879, when the hopes of utilising the electric current for lighting purposes were high but not yet practically realised, electricians were perhaps about equally divided as regarded methods of distribution. The chief apostles of the two schools were Charles F. Brush and Thomas A. Edison. The former advocated the plan of distributing by unvarying current, and the latter by unvarying potential. The former had met with considerable success with the arc lamp some time before the incandescent lamp became known to the public, and, so far as the operation of arc lamps was concerned, his success was as complete as was that of Edison later with the incandescent lamp. While Brush was working with large units intended to be distributed over large areas, Edison was working with smaller units intended for a more limited distribution, and each solved his own problem so satisfactorily that neither method has yet been supplanted in its own territory to any considerable extent by the other, although a borderland between the two territories has been occupied with varying degrees of success by both.

Brush employed a current of constant value, and arranged his lamps in series with each other and the source of energy so that the current passed through each in succession before returning to the generator, the increase of energy required by the multiplication of lamps being supplied by a corresponding increase in pressure at the generating station. This method had at least one recommendation: it admitted of a precise determination of the most economical size of conductors, which held the same relation towards economy so long as the cost of copper and steam power remained the same, whether there were two lamps burning or 50, or whether the line were one mile long or 30. Another recommendation, scarcely less important in the light of subsequent events, was that it permitted the extension of circuits at all times on the lines already laid down without disadvantage to or modification of those portions already constructed. It laboured at first under this great disadvantage, however, that since in his system every lamp formed an integral part of the circuit the failure of any disabled all and the minor irregularities of operation were cumulative. The solution of this difficulty was found in the cut-out or by-path provided in each lamp, through which the current was automatically shunted in case of failure of the carbons to feed. In this way the integrity of the circuit was maintained independently of the operation of the lamp, and the system has grown until now there is, theoretically, no limit to the number of lamps that can be placed on a circuit, each working independently of all the rest as though it were on an independent circuit. As a matter of fact, the Brush Company have recently constructed a machine intended to supply 125 2,000-c.p. lights from one circuit, and there are many circuits in nightly use upwards of 20 miles in length. The series system, however, is not adapted to the distribution of small currents such as are employed in incandescent lamps. While it has not been approached in its adaptation to the arc lamp, it has made little progress, and that little it has lost, in the incandescent field.

Edison, on the other hand, followed the method of gas and water distribution common in our cities and elsewhere, wherein a constant head or pressure is maintained and the increased demand for energy is supplied by an increase in the flow under the unvarying head. By this method the capacity of the mains must be gauged by the sum of the individual demands; in planning an installation provision must be made for the future, and when that provision is exhausted additional mains must be laid to meet the increased demands. This method had the recommendation of greater flexibility, permitting the supply of all-sized individual demands from the same mains with practically independent circuits for each individual translating device. It had the disadvantage, however, of requiring much larger investments in copper, which increased under some circumstances as the square of the demand in current, and shared with our methods of gas distribution the faults of loss of pressure as the distances increased, especially in cases where the drain upon the mains was large near the source of energy. For this reason the areas that could be supplied from centres of generation were exceedingly limited, though the method was sufficient for the early requirements. As the areas to be covered increased, the ingenious device was resorted to of dividing them up into smaller areas, whose centres were supplied by feeders and mains at the proper potential at their terminals for use throughout the local areas, and thus, and by means of the three-wire system which permitted the distribution of current at double the potential at which it was to be used, the areas that could be economically supplied with current for the incandescent lamp have become comparable to those already covered by water and gas.

But with the advent of the electric railroad new problems were introduced. It was not so much areas as distances that now must be covered, and with the extension of these lines to the suburbs and the growing demand for interurban electric

Digitized by Google

lines these problems become more and more urgent of solution in a different and more effective manner than hitherto.

Brush stopped with his discovery of the automatic cut-out for stationary translating devices, and without an equivalent for the moving car the constant-current system lacked sufficient flexibility. On the other hand, with the constant-potential method it was only necessary to double or treble the potential to give equally economical distribution to double and treble the distance. Five hundred volts (about five times that upon which incandescent lamps can be used) was decided upon as within the limits of safety, and has become the standard street railway pressure throughout the country. By this means, with the assistance of feeders, even suburban requirements up to 11 or 12 miles (in one extreme instance) have been supplied, but now come the further requirements of interurban lines, which can only be met by this system by a duplication or multiplication of generating stations, with all that is implied thereby. In these longer distances, the constant-potential method, if it has not already done so, is certainly beginning to trench upon a domain which does not belong to it, as we shall attempt to show.

The problem of distributing current to moving cars by the constant-potential or multiple-arc system is quite different from that of distributing current by the same method to stationary translating devices, in that the position of the load is constantly changing. The cars at times may be all bunched at the further end of the line, and the feeder provision must be sufficient to meet this contingency. If sufficient for this, it involves an investment in copper so much in excess of the mean requirements as to be a heavy burden on the interest charges. Such a heavy burden is this, in fact, that, when the distances exceed eight or ten miles, it is usually deemed more expedient to erect a second station, with all that that implies, than to make use of sufficient copper to overcome the drop that would otherwise result.

It will be evident that in calculating the copper for an installation of this kind, having a constantly varying and shifting load, the best we can do is to proportion it to certain ideal requirements, which may in practice be met only once or twice in the day's run. For all other conditions the amount of copper employed will not be that which will meet the requirements of maximum economy.

In the multiple-arc system it is dangerous to reverse the direction of motion of the motor while the car is rapidly moving, and hence advantage cannot be taken of electrical braking except in cases of emergency. The moving car is always checked by mechanical means, and in descending a grade its energy of position is entirely frittered away in heat on the brake shoe and wheel tyre.

The single trolley is all but universally used, thus making the track and earth a part of the circuit. This introduces an element of uncertainty in the circuit which can never be provided for adequately by the overhead system of feeders and trolley wire, and one which has caused no end of annoyance. When the ground is soaked in water, the resistance of this return is almost negligible ; but when it is dry and parched, or when the track is covered with dry dust or dry snow, it may increase to almost any extent. To obviate these difficulties some companies have actually spent more money in the ground in the attempt to give a uniformly good return to the current than they have spent in their feeders and trolley wire overhead, and yet have failed to obtain an entirely satisfactory result.

Since the electric car has become almost universal in our larger cities a new and equally serious objection to the ground return has developed, in the corrosion of the gas and water pipes and metallic sheathing of cables buried in the ground, due to the electrolysis caused by the large currents. This has been especially noticeable in Boston, Cambridge, and Brooklyn, and no adequate remedy has as yet been devised, nor does there seem at present to be any remedy other than the radical one of abandoning the earth entirely as a return and resorting to the double-trolley system. The question of damages for the destruction of water and other pipes by the return currents from electric railways has not yet come up before the courts, but it would certainly seem that the trolley companies should be held responsible in equity, if not in law. It behoves us, therefore, to look about us for the means of abating that which is not only a nuisance to ourselves, speaking as street-railway men, but an injury to our neighbour, and it is for the purpose of calling attention to a system which appears to meet all the requirements that this paper has been undertaken.

Brush solved the problem of supplying arc lamps arranged in series on a constant-current circuit. He did not go into the street-railway problem on the series method, but his successor, Prof. Sidney Howe Short, made a most determined effort towards its solution and actually constructed and operated for a time two small roads on constant-current circuits. While his plan proved a failure as a practical system, the results obtained were exceedingly instructive, and demonstrated that, if the series system could be made as flexible as the multiple-arc, it would possess many features of economy, both in construction and in operation, to recommend it far above the latter for traction distribution.

In regard to the series system, the following advantages have, I believe, been fully proved, and are admitted by all :

1. The installation of the power station is by far simpler and less expensive than that of a station on the multiple-arc plan.

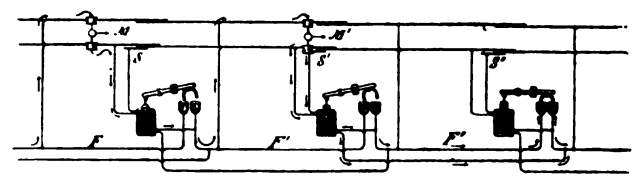
2. Where high potentials are used, as is necessary in long transmissions, both the dynamos and motors are smaller and cheaper to build than those of the same capacity suitable for constant-potential circuits.

3. The amount of copper required for transmissions of equal amounts of power to equal distances is considerably less in the series system, and its weight, having been once determined to best meet the question of economy, continues to meet that question equally well, whether there be one car or many on the line and whether the line be one mile in length or 30. In fact, since the current remains the same, the question to be solved always is merely what size of wire will, all things considered, most economically carry that current, and this will be determined and hold good irrespective of the number of cars, the length of the line, or the position of the cars on the line. In the multiple-arc system (that now in universal use) the same economy could be obtained only by varying the copper with the constantly-changing position and demand of the cars, which is, of course, an impossibility. In the series system it is obtained by simply varying the E.M.F. of the circuit to meet the ever-changing conditions, and this is automatically attended to by the dynamo itself.

4. It is in many respects safer, for, while high potentials are used in the series system, they are confined to the terminals of the dynamos in the power station, and the potentials at the car terminals are only proportional to the work which each car is doing at the time, while in the multiple-arc system the high potentials extend to the terminals of every motor on the line, irrespective of whether it is doing much work or little.

The other advantages will be mentioned at the proper place in the description of the method which follows.

In a system which has been devised recently the main features are that a system of feeders is employed as in the multiple-arc system, which, instead of feeding amperes into the trolley wires, as in the latter, feeds in volts or E.M.F. This may seem to be a rather strange statement to make in regard to a series system, but it will be better understood by reference to Diagram No. 1. F F′ F″ is the main circuit or feeder wire,



normally electrically continuous and independent of the trolley wires above. It is, however, divided into sections, each of which is terminated by a mercury-cup, into which take the copper forks by which these sections are normally connected electrically. The two trolley wires—for this is a double-trolley system—are also divided into similar sections or blocks, the adjacent ends of both wires of adjoining blocks being lapped, but insulated from each other, and the laps are staggered as shown. The further trolley wire of the block is directly connected with one section of the feeder, and the near wire is connected through the coils of an electromagnet with the succeeding sections of the feeders.

Also parallel to the nearer lap, and anticipating it a little, is a short subsidiary wire, S S′ S″, which is connected with a second coil of the same magnet wound parallel with the first, and which in its prolongation short-circuits the mercury-cups of the next succeeding section in advance. The above electromagnets, when excited, raise the forks in the corresponding mercury-cups, breaking the feeder circuit at that point and forcing the current to take another path. As the trolley-wire sections are normally insulated from each other, no current can ever pass through the magnet unless there be a car on that section. The car motor therefore forms the alternative path through which the current has to pass when the fork is raised. In Diagram No. 1 these features are shown, together with cars, M M′, on adjacent trolley blocks. The arrows show the paths pursued by the current, and also how the two cars are thus arranged in series with one another.

It will be noticed that the supplemental conductors and the laps in the trolley wires are so arranged relative to each other that when a car is travelling in the direction of the main current, the trolley travelling upon the wire connected with the fork or switch will contact with the supplemental conductor before reaching the lapping portion of the trolley wires, and the companion trolley will reach its lap after the first trolley has reached its lap and before it has passed beyond the supplemental conductor, while with a car travelling in the opposite direction, the order will be reversed—the trolley upon the wire not connected with the switch first reaching its lap, after which its companion trolley first reaches its lap, and afterward the supplemental conductor. In

Digitized by Google

this manner the transition is accomplished in either direction from one section to another, either on the same or another circuit, without spark or interruption of circuit. In fact, there is here accomplished for the series railway car what Brush accomplished for the series arc lamp.

As the number of cars operated on one circuit will be limited by the potential it is deemed safe to have at the dynamo terminals, the road is divided up into as many working sections as may be deemed advisable, each of these sections, one of which may consist of many blocks, being operated on a separate circuit. In this way the potentials may be kept within limits.

It is intended that but one car shall occupy a block at a time. Since the block receives current only while occupied by a car, the entrance of the car on the block may set a signal of danger, which is withdrawn on its leaving that block. If, however, notwithstanding the danger signal, a second car should run on to the block, the two would be thrown into multiple with each other and both brought quickly to rest, thus constituting this system a most perfect block system.

The series car is controlled entirely by shifting the position of the brushes. The current being constant, it is perfectly safe to reverse the position of the brushes, even at full speed. By this operation the motor is converted into a dynamo in series with the one in the power station, and contributes E.M.F. to the line to the last turn of the wheels. Instead of frittering away in heat the energy due to the acquired motion of the car, as in the multiple-arc system, the car is checked by reversing the brushes, and the energy absorbed by thus checking its motion is thrown on to the line for use elsewhere or to the relief of the steam-engine. In descending a grade, too, the energy stored up in the car as potential in ascending that grade is given out to the line as kinetic energy instead of being thrown away as at present. Since in a round trip there is much down grade as up grade, the track is theoretically reduced to a level; and since the car is checked as often as it is accelerated, its motion is theoretically reduced to a continuous and uniform one, and the economies resulting from these ideal conditions are by this system, and by this system alone, theoretically realised. Practically, the economies of operation must be very large, though, of course, far short of the theoretical.

One of the greatest doubts that I have had in regard to this system concerned the ability of the generator to respond promptly to the enormous sudden changes in potential corresponding to the similar changes in current on multiple-arc roads. This doubt has been entirely removed by the experience in a series transmission plant at Geneva which has been in successful operation for nearly two years. Although this plant is driven by water power, the diagrams show that, while instantaneous fluctuations of 1,000 volts were frequent—on several occasions the variation was between 1,400 and 5,800 volts—the regulation was effective and practically instantaneous.

It is believed that this recent improvement renders the series system fully as elastic as the multiple-arc system, and that in view of the difficulties encountered in the latter, the growing tendency to extend electric railroads to greater distances, and especially in view of the recent decision by Judge Greene in the feeder and main patent, awarding the sole right to use feeders to the Edison Company, aside from its own intrinsic merit, this system will soon attract the attention it deserves of the electrical public.

TRADE NOTES AND NOVELTIES.

FIRE EXTINCTION.

It is always advisable for engineers in central electric light stations and in private installations to be prepared in case of an outbreak of fire, and the annexed illustrations show two neat and useful sets of fire-extinguishing appliances, which can be placed in odd corners so as to be ready at hand. Fig. 1 shows an arrangement consisting of four fire-buckets and a portable

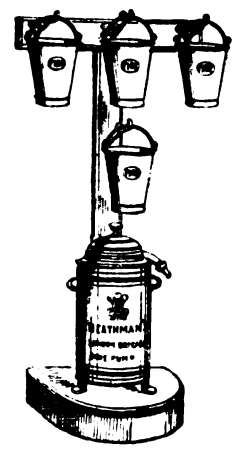


FIG. 1.

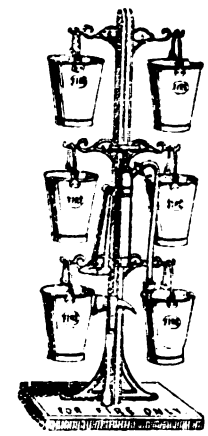

FIG. 2.

hand fire-pump complete upon a stand—the pump will throw a jet 35ft.; and Fig. 2 represents a set of six buckets and a foot bracket fire-pump to work from any bucket, while there is a hatchet available to sever electric casings and wires. Messrs. Heathman and Co., of Endell-street, London, W.C., are the makers.

BRADFORD CORPORATION ELECTRICITY SUPPLY.

Mr. James N. Shoolbred, B.A., M.I.C.E., has communicated to the Society of Arts the following tables in reference to the discussion on Prof. Robinson's paper on "The St. Pancras Electric Lighting Installation," and in continuation of the information in his own paper on "The Bradford Corporation Electricity Supply," read May 4, 1892:

In an analysis (given by Mr. Crompton in *Lightning*, January 4, 1894) of the cost of supplying electricity in England in 1892, he finds that at 12 central working stations with "continuous" currents, the average capital expended per unit sold was 5s. 1½d.; while at the nine stations working with "alternating" currents, the average was 8s. 8d.

PHYSICAL SOCIETY.

At a meeting of this society, on the 9th inst., Prof. A. W. Rücker, F.R.S., president, in the chair, **Prof. S. Henrici, F.R.S.**, made a communication on "**Mathematical Calculating Machines, Especially a New Harmonic Analyser.**" After mentioning the general principles on which such machines are based, the author showed a new arithmometer devised by Prof. Selling, in which the jerky motions of the numeral wheels common in such instruments are eliminated, and the operations simplified. Another arithmometer of very compact design, named the "Brumviga," had been placed on the table by Prof. Boys. The simple and ingenious "Hatchet" integrator was then shown. It resembles a small hatchet, with a tracing-point projecting at right angles to and at the end of the handle. Moving the point from near the centre of mass of any closed curve, round the curve once and back to the starting point, the distance between the initial and final positions of the hatchet head is a measure of the area of the curve. The instrument has been found very useful for indicator diagrams. A Hine and Robertson's planimeter, lent by Prof. Perry, an Amsler planimeter combined with a pentagraph for measuring small areas, an Amsler integrator to give areas and first moments, and a beautiful sphere and cylinder rolling integrator of great accuracy by Coradi of Zürich, were shown, as well as an ingenious integraph devised by Abdank Abakonowitcz. Passing on to harmonic analysers, Prof. Henrici explained the object of such instruments—viz., to determine the coefficients in Fourier's expansion for any periodic curve :

$$y = A + A_1 \cos\theta + A_2 \cos 2\theta + \ . \ . \ + B_1 \sin\theta + B_2 \sin 2\theta + \ . \ .$$

and briefly described Lord Kelvin's instrument now in use at the Meteorological Office. This machine gives the first term and three pairs of coefficients, A and B, but is large and expensive. The author had endeavoured to devise a simple and more portable instrument, and now described the various stages in the evolution of his new analyser. Using Clifford's method of wrapping the curve round a cylinder, he saw that by imparting a simple harmonic motion to a plane tangential to the cylinder, which plane carried an Amsler planimeter whose tracing-point followed the intersection of the plane with the curve as the cylinder rotated, any coefficient, A*n* or B*n*, could be determined. This arrangement had considerable friction, and only gave one coefficient at a time. It also necessitated readjustment of the period of the harmonic motion for each pair of terms. Another machine, founded on integration by parts, was then constructed, in which the relative periods of cylinder and registering wheels was adjusted by a disc and roller, the motion being transmitted to the wheels by bands driven from the disc spindle. This gave A*n* and B*n* at one operation. Mr. A. Sharp used this machine for some time, and then designed an inversion of it, in which the curve was laid out flat and the machine rolled over it. This arrangement greatly facilitated the multiplication of registering wheels, and enabled several pairs of coefficients to be determined at once. The first machine of this kind showed several small errors, which were avoided in a second instrument, a specimen of which, made by Coradi, was exhibited and described. A rectangular frame, carried on three rollers (two being fixed to the ends of a long axis), traverses the paper in the direction of y, and the tracing-point is fixed to a carriage which moves on the frame in a direction perpendicular to y—*i.e.*, in the direction of θ. A band is attached to this carriage and imparts a motion proportional to θ to two horizontal areas (one for the A coefficients and one for the B's), placed above and parallel to the long roller axis above mentioned. Each of the two axes carries five pinions having teeth in the ratios 1, 2, 3, 4, 5 respectively, which gear with crown wheels fixed to vertical spindles. The latter, therefore, rotate through angles proportional to θ, 2θ, 3θ, 4θ, and 5θ. To the lower ends of these spindles horizontal rings are attached, in which the bearings of a registering wheel are formed. Each wheel rests on a cylinder carried by the long axis, and rolls or slides thereon according as its axis is parallel or perpendicular to that of the cylinder. Moving the tracing-point once round the curve gives five pairs of coefficients. By changing the driving band to other pulleys, so as to turn the pinions at different rates relative to the θ movement, the sixth, eighth, tenth, and seventh and ninth pairs can be obtained. The chief drawback of the instrument is that the registering wheels are not easy to read, whilst the backlash of the crown wheels and pinions introduces small errors. In the latest form of instrument toothed wheels are dispensed with, and glass spheres carried in frames on the vertical spindles roll on the horizontal cylinders. Each sphere actuates two registering wheels on fixed axes at right angles to each other, and these give respectively the sine and cosine coefficients. The number of vertical spindles is therefore halved, and the instrument greatly simplified. These details have been introduced by Coradi. A working drawing of another analyser designed by Mr. Sharp, which gives the amplitude and epoch of the curve resulting from each pair of terms in Fourier's expansion, was exhibited. The discussion on Prof. Henrici's communication was postponed until next meeting.

Mr. H. Wilde, F.R.S., then exhibited and described his "**Magnetarium.**" This consists of a hollow geographical globe wound all over the inner surface with insulated wire in planes parallel to the equator. Within this globe is a sphere wound with wire on its surface, and having its axis inclined at 23½deg. to that of the outer globe. By means of epicyclic gearing the spheres can be made to rotate at slightly different rates. When electric currents of suitable strength are passed through the two windings, the magnetic condition of the earth can be imitated, both as regards distribution at any epoch and the secular variations. A better result was obtained by putting sheet iron over the land areas, and a still closer approximation by using thin iron over the water areas. A magnetic chart and tables giving the magnetic elements at various places for different epochs were shown. The author mentioned that recent observations by the United States Survey at Ascension Island, and by Prof. Thorpe in Senegambia, had confirmed results obtained by the magnetarium. The **President** said he had tried the apparatus, and found the Siberian oval closely imitated. The secular variations at Greenwich were also well shown. In South America the approximation was not so good. In reply to a question by Mr. Blakesley, **Mr. Wilde** said the present position of the pole of the inner sphere was 84deg. west, 67deg. north.

COMPANIES' MEETINGS.

CAMBRIDGE ELECTRIC LIGHT SUPPLY COMPANY, LIMITED.

The annual meeting of this Company was held last week at the Company's offices, 2, Sidney-street, the Rev. G. B. Finch, chairman, presiding.

The report of the directors was as follows :

"Your directors have pleasure in reporting that the prospects of the Company are satisfactory. During the last six months lamps equivalent to about 6,000 lamps of 10 c.p. have been connected to the Company's mains, making a total at the present time equal to 8,000 lamps of 10 c.p., and there is every prospect that the number will be largely increased during the present year. The plant during the last three months has been fairly loaded, and has worked to the satisfaction of the directors; but, owing to the coal strike in the autumn, a considerably increased price had to be paid for fuel. It seemed to your directors that it would be inexpedient to commence a profit and loss account, in respect of supply of energy, with only a small portion of the machinery at work, and they have therefore deemed it advisable to carry all receipts and expenditure under this head up to June 30 last to capital account. The Company has made a profit of £268 to December 31 last, and it is anticipated that with the additional lamps lately connected and those which will shortly be connected, your directors will be able at the next annual meeting to advise the payment of a substantial dividend for the current year. Your directors have thought it necessary to apply to the Local Authority for their sanction to the temporary suspension of the supply of current, between the hours of 2 a.m. and 5 p.m. in summer, and 2 a.m. and 6 a.m. in winter. A supply during these hours will involve the shareholders in heavy additional expenditure at the present early stage of the Company's operations, without any corresponding benefit to the general public. Your directors, however, hope that the applications for current will shortly be sufficient to justify them in making the supply continuous, and it will be their endeavour to effect this at the earliest opportunity. The Rev. G. B. Finch and Mr. J. Simpson retire by rotation; the latter is eligible and offers himself for re-election. The directors also recommend the election of Dr. P. W. Latham and Mr. W. C. Hall."

The **Chairman**, in moving that the report and accounts be

Digitized by Google

received and adopted, stated that he thought they might say that the anticipations which they all had at the outset had been even more than realised by the success of the Company. The statement in the second paragraph of the report was certainly very satisfactory to the town. They had had applications for many more lamps, and the work of extension showed no signs of being arrested. The colleges were beginning to take the light for the rooms of the undergraduates. That had been going on for some little time, and when once that was established they expected they would find some of their best customers amongst the residents in the rooms of the colleges, and that they would get a very good return from the lamps in the students' rooms. There was a feature in the report which they ought not to pass over, and that was with regard to carrying all receipts and expenditure under the head of profit and loss up to June 30 to capital account. The directors thought it would be much better to treat all receipts and expenditure as belonging to the capital account up to a certain date. They hoped that the shareholders would agree with the course adopted. Alluding to the sixth paragraph in the report, the Chairman said they all knew that in the summer months they could not carry on the concern so as to make a profit at the present time, and that was the experience of all companies at the beginning. During the summer months at Newcastle the losses had been gradually dwindling down, until at last there was no loss whatever. They were so situated that they made a profit all the year round. They anticipated, after a little time, that that would be the case in Cambridge. At Newcastle 5½ per cent. was paid, and the Newcastle company was established two or three years before the Cambridge Company. From October 1 to February 20 last the Company made a profit of £768. The coal strike imposed a burden of £50 a month upon them which otherwise they would not have had. If it had not been for the coal strike they would have had a profit of £918 in the five months. He thought that that justified the statement made at the commencement of the report that the prospects of the Company were satisfactory. The shareholders would notice the following item in the balance-sheet, "Debentures, £7,000 at 5 per cent."; £7,000 was a sum borrowed from Fosters' bank, and they held a charge over the Company's property. It was called a "debenture," but that was a misprint; it should have been described as a debt owing to Fosters. What the directors desired to do now was to raise a sum not exceeding £10,000 on debentures of 4½ per cent., and offer the debentures to the members of the Company in the first instance on terms to be afterwards appointed. They did not entertain any doubt of their ability to raise the money, but they hoped it would come from the shareholders in preference to any persons outside. Probably they would be offered *pro rata*, but inasmuch as some might not be expected to take up their proportion, the shareholders would be asked to signify how much they would be willing to take. Referring to the last paragraph of the report, the Chairman said he did not offer himself for re-election as a director; Mr. Simpson did, and he (the Chairman) hoped he would be reappointed. As regarded himself, he felt very great regret at retiring, but he did so for the same reason that induced him to retire from the Town Council. One regret certainly it was that he would not any longer transact business with persons whom he found it so pleasant to meet under all circumstances. That would be his chief regret in the matter.

Sir Benjamin Browne seconded the adoption of the report.

The **Hon. C. A. Parsons**, in answer to several questions put by Mr. Young, explained that the expenditure had been kept down to the very lowest figure. A large number of new lamps were coming on, and they hoped to run during next summer without any loss at all in the working expenses. They had laid 18½ miles of single cable, and 5½ miles of piping, which was exactly the same amount laid at Scarborough, and the total expense was within £200 of each other. The works had been carefully carried out in both places. At Newcastle they had about six miles of piping, but they had about 28 miles of cable, and there they supplied over 18,000 lamps at the present time. The cost of the Cambridge station had been a little more than the Newcastle station, the difference arising chiefly in the building, and in a larger expenditure on provisional orders and preliminary expenses. At Newcastle they saved a great deal in building; they took old buildings already there.

The report was then put to the meeting and adopted.

Mr. Matthew proposed the appointment of Mr. J. B. Simpson, Dr. P. W. Latham, and Mr. W. C. Hall as directors.

The proposition was seconded by **Mr. Barrett**, and agreed to.

On the motion of **Mr. Bowes**, Mr. Arthur Rutter was re-elected auditor.

Sir Benjamin Browne said that the question of the remuneration of directors was considered at the last meeting, and it was decided that it had better stand over for a year. He proposed that the sum of 150 guineas be set aside as remuneration for the board of directors of the Company up to the present time. The motion was seconded and carried.

BIRMINGHAM ELECTRIC SUPPLY COMPANY, LIMITED.

The ordinary general meeting of this Company was held last week at the offices, Dale End, Mr. Henry Buckley, presiding.

The **Chairman**, in moving the adoption of the report and statement of accounts, which were published in our last issue, stated that the Company, like most others, had suffered from the coal strike. It was only fair to assume that in a time of general commercial depression shopkeepers and others were not so willing to incur capital expenditure in lighting alterations if they could avoid it. However, shareholders might take hope from the latest Board of Trade returns that brighter days were opening, and the Company, no doubt, would share in any improvement in business. But notwithstanding the past depression, the Company during the past year had made satisfactory progress, although there had been phenomenally clear days through the winter months. At the end of 1892 the Company had an equivalent to 8,329 16-c.p. lamps. At the end of 1893 the number was 10,223, and there had since been a further increase of 1,000. The consumers in the same time had increased from 223 to upwards of 300, and the current, measured by units, had increased from 214,088 to 352,096. The percentage of increase had been—in lamps 22·7, in consumers 30·3, and in current 64·5. The sum placed to reserve accounts compared most favourably with other companies. The directors were doing well to deal liberally under that head. Last year he referred to the question of new areas—Edgbaston, the residential section, and the jewellers' quarters. The question at that time was deferred in deference to the City Council. At their July meeting the matter was brought up, and the scheme was practically approved, with the exception of certain clauses, which were to be discussed between the Company and the Council committee. It was now hoped that if there was no dissolution the Company would be armed with the necessary parliamentary powers, and be then in possession of the areas, which he felt sure would prove beneficial to the Company.

Mr. C. A. Harrison seconded the motion, which was agreed to.

The retiring directors and auditors were re-elected, and the proceedings closed with a vote of thanks to the directors.

HOVE ELECTRIC LIGHTING COMPANY, LIMITED.

The second annual general meeting of this Company was held on Wednesday at Hove, Colonel H. Woods, C.B., the vice-chairman of the Board of Directors, presiding.

The **Chairman**, in moving the adoption of the report and accounts, which were given in our last issue, congratulated the shareholders on the continued satisfactory progress of the Company. As they would have seen from the report, the number of lights connected continued to increase, and it was expected that before the end of the current year the number of lights would be more than double the number on December 31 last, and that they would then have 14,000 or 15,000 connected up. The exact number now was 12,600. When it was considered that the actual expenditure of the Company would probably at that time not exceed £35,000 or £40,000, it must, he thought, be admitted that, compared with what was done by many other companies, this was extremely satisfactory. In addition to the private lights, it was hoped that before the end of the year the Hove Commissioners would put up some public lamps along the front, if not in some of the streets, and this would add materially to the business of the Company, and be an advantage to the public in Hove. The success of the Company was far in excess of what was anticipated, and the shares were consequently a good investment. But to ensure the continued success of the Company, and to enable them to meet the calls upon them by intending consumers, further capital was required. Hitherto their contractors, Messrs. Crompton and Co., had promptly executed all orders, and had met the directors in every way, but considerable extension was necessary on such a scale that it would not be prudent for the directors to enter into any fresh contracts unless further capital was subscribed. There was another matter upon which the directors were able to congratulate the shareholders—the retirement of the opposition company from the field, thus giving this Company the monopoly. The competition between the two companies had been both fair and straightforward, and now that the other company were retiring from the field they were advising their customers to come over to the underground system. Though they sympathised with the shareholders in the other company, they anticipated that the result of its withdrawal from the field would be that the Hove Electric Light Company would do more business. Dealing with the present condition of affairs, he said the directors proposed to offer the balance of the shares to the public, and at the same time issue a debenture prospectus. The shareholders would be asked to empower the directors to issue more debentures than by the articles of association they had now the power to do; but it was not intended to make a higher issue than £12,500 for the present, though it was proposed that this sum should form part of a total of £25,000 when the magnitude of the works justified the directors in making such an issue. He concluded by proposing the adoption of the report.

Mr. C. F. Tufnell seconded the motion for the adoption of the report and accounts, and the resolution was carried.

Colonel A. J. Filgate, R.E., and Colonel H. Wood, C.B., the retiring directors, were re-elected on the motion of **Mr. Tufnell**, seconded by **Mr. Albright**, the latter complimenting the directors on the manner in which they did their work.

Mr. Robert Payne, F.C.A., was reappointed auditor to the Company.

The **Chairman** then proposed: "That the directors be and they are hereby empowered to borrow or raise any sum or sums of money on such security and upon such terms as to interest or otherwise as they may deem fit, and for the purposes of securing the same and interest or for any other purpose may create, issue, make, and give respectively perpetual or redeemable debentures or debenture stock, or any mortgage or charge upon the undertaking or the whole or any part of the property, present or future or uncalled capital of the Company, provided that they shall not without the further sanction of a general meeting of the Company borrow or raise any sum of money exceeding in the whole £25,000."

Mr. Tufnell seconded, and the motion was agreed to.

COMPANIES' REPORTS.

W. T. HENLEY'S TELEGRAPH WORKS COMPANY.

Report of the directors to be presented to the shareholders at the ordinary general meeting, to be held at the Company's offices on Thursday, March 22, at 2.30 p.m.

The directors have pleasure in submitting their annual report. The annexed accounts show that a net profit has been made of £10,777. 6s. 2d. After payment of interest and income tax, and making allowance for depreciation of plant, there remains £7,256. 14s. 1d., to which must be added £13,399 10s. 1d. brought from last year. Deducting £1,050, the half-year's dividend on preference shares paid in October last, there remains a disposal balance of £19,606. 4s. 2d. The directors have added £10,000 to the reserve fund, and they propose the payment of a further half-year's dividend on the preference shares at the rate of 7 per cent. per annum, and a dividend for the year at the rate of 5 per cent. free of income tax on the ordinary shares; these payments together absorb £4,468. 10s., and leave a balance of £5,137. 14s. 2d. to be carried forward. A further sum of £4,000 has been paid off the £30,000 B debentures created in 1891, which has reduced their amount to £12,000. The improvements and extension of the Company's factories at North Woolwich, which were contemplated when the preference capital was subscribed, have been completed, and the buildings, machinery, tools, etc., of the Company are now in first-class condition. The general business of the Company has been satisfactory, and a few hundreds of miles of submarine cables have been manufactured for various telegraph companies, and for the British Government. The directors who retire on this occasion, in accordance with the provisions of the articles of association, are Mr. Frederick Newton and General George Hutchinson, C.B., C.S.I., and, being eligible, they offer themselves for re-election. The meeting will appoint auditors for the ensuing year.

PROFIT AND LOSS ACCOUNT, YEAR ENDING DEC. 31, 1893.

BUSINESS NOTES.

Western and Brazilian Telegraph Company.—The receipts for the week ended March 9 were £3,252.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 11th inst. amounted to £687.

Fire.—A fire has occurred at the Hope Jones Electric Organ Works, Birkenhead. Damage to the extent of about £1,000 was done.

Sale of Cadby Hall.—Cadby Hall, the premises of Woodhouse and Rawson, Limited, at Kensington, will be put up to auction by Messrs. G. A. Wilkinson and Son next month.

The Tenders for Edinburgh.—To-morrow (Saturday) is the last day for receiving tenders required by the Corporation of Edinburgh for work in connection with electric lighting.

Dorset.—At a meeting of the County Council it was reported that the new asylum was rapidly approaching completion. The contract for electric lighting has been 1st to Mr. F. M. Newton, of Taunton.

Tender Accepted.—The tender of Messrs. Penman and Co., of Glasgow, has been accepted for the supply of a Cornish boiler for the electric light station, Abercorn Basin, for the Belfast Harbour Commissioners.

Harrogate.—The town clerk has been instructed to confer with Mr. Wilkinson, the electrical engineer, and have the agreement for carrying out the contract prepared and submitted to the General Purposes Committee.

Oriental Telephone Company.—The Oriental Telephone and Electric Company confirmed on Monday the resolutions passed at a meeting last month, directing the winding up of the Company for the purpose of reconstruction.

Stock Exchange Quotation.—An application has been made to the Stock Exchange Committee to appoint a special settling day in, and to grant a quotation to, the City of London Electric Lighting Company, Limited, for their £100,000 5 per cent. redeemable debenture stock.

Lifting Machinery.—Messrs. Barry and Higham, of Broad-street House, Old Broad-street, E.C., inform us that they have been appointed London agents for the crane and various lifting machinery manufactured by Mr. Thomas Smith, of Steam Crane Works, Rodley, near Leeds.

Electric Lighting of Tramcars.—As stated in our last issue, the general manager of the Glasgow Corporation Tramways invites tenders for the electric lighting of about 240 tramcars for one or more years. Communications to be sent to Mr. John Young, City Chambers, Glasgow.

Cheltenham.—The Electric Lighting Committee of the Town Council has been remodelled as follows: Aldermen Captain Griffith, Colonel Thoyts, and G. Norman, and Councillors King, Lawrence, Parsonage, Ward-Humphreys, and Woodard, the Mayor being an ex-officio member.

Tenders for Sutton.—The Sutton (Surrey) Local Board invite, by April 4, tenders for the purchase of the powers granted to them by the Board of Trade under the Sutton (Surrey) Electric Lighting Order. Further particulars can be obtained of the Board's surveyor, Mr. A. D. Greatorex, C.E.

City and South London Railway.—The receipts of the Company for the week ending March 11 were £930, against £859 for the same period last year, or an increase of £71. The total receipts for the first half-year of 1894 show a decrease of £58 compared with those for the corresponding period of 1893.

The Manchester Athenæum.—The Manchester Athenæum authorities are considering the question of lighting the building by electricity, and they have instructed Mr. Clirehugh, of Messrs. Wilson and Clirehugh, Temple-chambers, Brazenose-street, Manchester, to prepare plans and specifications for carrying out the work.

Malton.—A number of people gathered together last week to witness the reinstallation of the electric light at the works of the Malton Farmers' Manure and Trading Company, Limited, which were partly destroyed by fire three months ago. The electric light installation has again been put in by Messrs. Parr and Gillies, of Haggerston.

Eastern Telegraph Company.—The directors announce the payment on April 13 of interest of 3s. per share, less income tax, being at the rate of 6 per cent. per annum on the preference shares for the quarter ended March 31, and the usual interim dividend of

Digitized by Google

2s. 6d. per share on the ordinary shares, tax free, for the quarter ended December 31.

Leeds.—The Buildings Sub-Committee of the Town Council have had presented to them by the chairman a report on the cost of supplying the electric light from their own installation, and as to whether it was advisable to transfer the lighting to the Yorkshire House-to-House Electricity Company. The matter has been deferred for a month.

Lighting of Pumping Stations.—At the annual meeting of the General Hydraulic Power Company, Limited, Mr. H. Chapman said, with regard to providing the electric light, that the directors had decided in the first place to light up the City-road pumping station, and he believed they would thus be able to supply the light with advantage to the consumer.

Shop-Lighting.—A number of shops in Aberdeen has been fitted up with the electric light. In nine of these cases, the installation has been carried out by Messrs. New and Mayne, electrical and general engineers, under the personal superintendence of Mr. P. C. Middleton, their resident engineer. Messrs. New and Mayne have ready for lighting a further 22 shops.

Indian Agency.—Mr. Archibald A. Crawford, A.M.I.E.E., of Elphinstone Circle, Bombay, announces that he has been appointed general agent for India for the Allgemeine Elektricitäts Gesellschaft, of Berlin. At the same time he states that this enterprise will not interfere with his business in the many special fittings and other articles imported by him up to the present.

Commercial Cable Company.—The report for the year 1893 shows that the gross receipts were 1,842,346dol., the working expenses 784,600dol, and the net income 1,057,746dol. Dividends were paid at the rate of 7 per cent. per annum in respect of the year, absorbing 613,376dol., and of the remaining 444,370dol. the sum of 389,600dol. was applied in January last to the repayment of the remainder of the debenture bonds.

Islington.—The Clerk to the Islington Vestry mentioned at a meeting last week that he had been informed by Mr. Lewis, the solicitor, that the provisional contract with the Great Northern Railway Company had now been settled, and he asked the Vestry to advance £850 deposit money for the site for an electric lighting station. The request was referred to the Finance Committee, and it was agreed that the seal of the Vestry be attached to the provisional agreement.

Tenders for Boilers.—Tenders are required for the manufacture and delivery at their Neepsend works of three Lancashire steel boilers, each 30ft. long by 7ft. 6in diameter, for the Sheffield United Gaslight Company, Neepsend Station. Copy of the drawing and specification, with form of tender, may be obtained on application to the engineer, Mr. Fletcher W. Stevenson, on payment of 10s. 6d. Tenders to Mr. Hanbury Thomas, general manager, Commercial-street, Sheffield, at the company's offices, by 31st inst.

Direct Spanish Telegraph Company.—The report of the directors for the half-year ended December 31 states that the accounts, after providing for debenture interest, show a balance to the credit of profit and loss of £4,996. After adding the usual sum of £2,500 to the reserve fund, the balance of profit and loss amounted to £2,496, out of which a dividend at the rate of 10 per cent. per annum on the preference shares, and a dividend at the rate of 4 per cent. per annum, free of income tax, on the ordinary shares, is recommended.

Burton.—At a meeting of the Town Council last week Alderman Lowe moved the adoption of the report of the Gas and Electric Lighting Committee. He said that the introduction of the electric light in the town was a great success ; the only regret experienced about the scheme was that the customers were not numerous. The committee, however, felt sure that when the satisfactory nature of the new illuminant became generally known there would be a great influx of applications for its use. Councillor Turner seconded the motion, which was passed.

Appointment Open.—The Corporation of Belfast invite applications for the post of resident engineer for central electric lighting station from gentlemen who have had a thoroughly practical training both as mechanical and electrical engineers. Candidates should have had practical experience in central-station work, and also, if possible, in the laying of electric light mains. The salary will be £250 per annum. A schedule of duties will be sent by the town clerk on application. All applications should be in the hands of Sir Samuel Black, town clerk, by 20th inst.

Canterbury.—The following report of the Electric Light Committee of March 1 was submitted to a meeting of the Town Council last week: "A letter was read from the Brush Electrical Engineering Company, asking the Corporation to give them an extension of time for forming the Canterbury Electricity Supply Company. The committee recommend that an extension be granted until June 30, 1894, and that a letter be written expressing a hope that the company intend shortly to issue a prospectus, as until that is done the whole matter is at a standstill." The report was adopted.

Portsmouth.—The Electric Lighting Committee last week submitted to the Town Council certificates from Messrs. Waller and Manville for payment to the contractor for building (Contract No. 1), of the sum of £250, and to the contractors for boilers, engines, and electrical plant (Contract No. 2), of the sum of £1,350, and to the contractors for conduits, etc. (Contract No. 3), of the sum of £2,587, and recommended that such amounts be paid. The committee further recommended that they be authorised to appoint such officers and workmen as are found to be required in connection with the electric lighting in the borough. The report was adopted.

Mill-Lighting.—Messrs. Bennett and Druce, Preston, have received instructions from Messrs. Horrockses, Crewdson, and Co., Limited, the well-known cotton spinners, to instal a complete system of electric light in the new mill in course of erection. The plant will consist of three 500-light dynamos—two of which will be driven by the main engine, and a third off a special vertical engine. An interchangeable system of wiring has been devised by Mr. Druce, of this firm, so that complete failure of the light will be an impossibility. About 900 lamps will be installed in the mill, and the whole promises to be one of the largest and most complete mill installations in Lancashire.

Brighton.—The accounts of the electric lighting department for 1893 were submitted at the last meeting of the Town Council. Alderman Moon said the amount carried to the net revenue account was £4,011, out of which there had to be paid as interest on redeemable stock £2,058, and the amount transferred to loans fund and accrued due to date was £1,653 ; leaving a balance of £300 to be carried to net revenue. This, as a result of the second whole year's working, was not unsatisfactory. The number of houses connected with the system in 1892 was 215, and that figure had since been nearly doubled—being now 423. The total number of units sold in 1892 was 156,048 ; and in 1893, 286 895.

Shirley and Freemantle.—At the last meeting of the Local Board of Health, the Chairman proposed that the question of lighting the district with electricity be referred to the General Purposes Committee for consideration, and to report on the most economical means of doing the same. He said he did not think that they would have to pay more, and he thought there might be a considerable reduction in the cost of lighting in the district by electricity instead of gas. Mr. Ollis seconded the proposition, stating that it was thought sufficient water power could be obtained to give the motive power necessary to obtain the electric light, and then it could be got at the cheapest possible cost. The proposition was unanimously adopted.

Acton.—The Chairman of the Local Board stated at a meeting last week that he had been asked by a local paper to say something as to what the Board were doing in the matter of the lighting of the district by electricity. The Board were about to enter into an agreement with a Mr. Medhurst on the subject, and under that agreement the streets of the district would be lighted by electric light at the same rate as the Board were now paying for gas lighting. He did not think the Press could ask the Board to say more than that at the present moment. What he had said showed that the Board were doing something, and it was likely the agreement he had alluded to would be entered into, and, if so, would be carried out within the present year.

Elmore's German Company.—An extraordinary general meeting of Elmore's German and Austro-Hungarian Metal Company, Limited, was held on Monday at Winchester House for the purpose of passing resolutions to the effect that the second special resolution passed in June, 1892, be rescinded, and that the new shares authorised to be created by the first special resolution passed at that time, and the 25,000 shares now unissued of the original capital of the Company, should be called preference shares. After some discussion the resolutions were passed conditionally, the directors agreeing not to carry them into effect if an alternative scheme which was presented (having been prepared by Mr. Elmore) could possibly be carried out.

Edison and Swan United.—The directors of the Edison and Swan United Electric Light Company, Limited, have resolved to recommend a payment on account of the dividend of the current year at the rate of 5 per cent. per annum, less income tax, on the A shares of the Company, for the half-year ended December 31, 1893. This will work out as follows: On the 89,261 ordinary shares, £3 paid, 1s. 6d. per share ; on the 5,000 shares, £5 paid, allotted to the Edison Electric Light Company, Limited, 2s. 6d. per share ; on the 12,139 shares £5 paid, allotted to the Swan United Electric Light Company, Limited, 2s. 6d. per share. The payment will be made upon the register as it stood on the 13th inst., and the dividend warrants will be issued on the 20th inst.

Willans and Robinson, Limited.—This Company has been registered with a capital of £300,000, divided into 30,000 £6 per cent. cumulative preference and 30,000 ordinary shares of £5 each. The object is to acquire the business of Messrs Willans and Robinson, Limited, carried on at Thames Ditton, Surrey, and to carry on the business of mechanical and electrical engineers. The first signatories, with one share each, are: Mark H. Robinson, Chatley, Fassett-road, Surbiton ; Sir Gilbert Clayton-East, Hall-place, Maidenhead ; Captain M. Riall Sankey, Arterberry-road, Wimbledon ; George W. Anderson, Fenwick-chambers, Liverpool ; Thomas O. Lazenby, Tiverton, Devon ; Percy A. Low, Maybury Lodge, Thames Ditton ; and J. E. Thore, Red Cottage, Thames Ditton.

Blackpool.—Messrs. John Fowler and Co , Leeds, have obtained the contract for the extension of the Blackpool Electricity Works. Two new tramcars are to be procured, either with separate motor trucks or on the bogie principle, and the open cars, which have not been a success on the line even during the summer, are to be disposed of. In the meantime, Mr. M. Holroyd Smith is directing the preparations for putting the tram line in complete repair preparatory to running it by electricity again. The eldest son of Mr. Ralph Rushton has gone into the office of Mr. R. Hammond preparatory to entering upon a course of training at Faraday House. The Free Methodist chapel in Adelaide-street will be closed for alterations after Easter Sunday ; the electric light is to be installed.

Bristol.—The Electrical Committee held their fortnightly meeting on Friday. The committee considered the desirability of

Digitized by Google

reducing the charge for current consumed in the daytime, and determined to reduce the price for current supplied between midnight and one hour before sunset to 4d. per unit. The current consumed under this arrangement will be ascertained by means of meters. The committee also determined to allow discounts off the quarterly accounts for current consumed after the 31st inst. on the following basis: on accounts of £50 per annum, 5 per cent; £100 per annum, 10 per cent.; £250 per annum, 15 per cent.; £500 and over per annum, 20 per cent. The secretary presented the statement of accounts required by the Electric Lighting Act to December 31, 1893, in the form prescribed by the Board of Trade.

R. Bolton and Co., Limited.—Under a winding-up order made last January against R. Bolton and Co., Limited, accounts have been issued showing total liabilities £2,259, a deficiency of £1,248 as regards creditors, and a total deficiency of £8,248 to the shareholders. The Company was formed in April, 1893, to purchase for £8,000 the business of a merchant, engineer, etc., previously carried on by Mr. Reginald Bolton. The nominal capital was £12,000, but no prospectus was issued. The causes for the failure are stated to be depression in business, owing to the low state of the Italian and Sicilian markets, where the chief business of the company was transacted, bad debts, and depreciation in value of a large stock of carbons. The creditors and shareholders met on Wednesday and elected the official receiver as liquidator to wind up the Company, with a committee of inspection.

A Question of Vibration.—On Tuesday and Wednesday, in the Chancery Division of the High Court of Justice, Mr. Justice Stirling had before him the case of Wise *v.* the Metropolitan Electric Supply Company. It is an action brought by the occupiers and leaseholders in Manchester-street, Manchester-square, to obtain an injunction against the defendants, whose electric light station is situated on the east of the street. It was stated by counsel on Tuesday that the vibration caused by the machinery was so great that families were shaken in their beds, clocks stopped, and the people who lived in the nearer houses were always liable to small electric shocks on touching certain articles in the houses. For the defence it was contended that efforts had been made to prevent the nuisance. Sir Richard Webster having opened the case for the defence on Wednesday, the further hearing was adjourned until the 24th prox.

Beckenham.—A report has been presented to the Local Board by Mr. Gisbert Kapp on the question of supplying the district with electric light, under the recently acquired provisional order. He recommends the Board to carry out an installation. The scheme is divided into two stages, and he bases his figures on the following estimates: that in the first stage 100 houses will be served, with 2,650 10-c.p. lamps, and a revenue of £1,260; and that in the second stage 460 houses will be supplied, with 13,500 lamps, and a revenue of £6,610. He recommends a high-pressure alternating-current supply, and places the capital expenditure on the first stage at £11,000, and on the second stage at £27,000. Mr. Kapp's estimate as to the working expenses shows that there would be a loss on the first stage, while on the second stage a profit of £2,717 would be realised. The Electric Lighting Committee of the Board are considering the matter.

Messrs. Hodges and Todd.—It is gratifying to note that, notwithstanding the reports one hears in some quarters of general depression of business, some firms are extending their operations. We learn that Messrs. Hodges and Todd are doing so, for in addition to their Turnmill-street premises (which are inadequate for their increased business), they have taken extensive works at 30-42B. Hampstead-road, where they have ample facilities for manufacturing their various specialities of measuring instruments, switchboards, etc. These works are run by electric motors of the Immisch type, the current being obtained from the St. Pancras Vestry's mains, and which it is thought will prove to be as economical as any other form of motive power, whilst at the same time a great saving in time and labour is effected. The main switchboard which controls the whole shops is fitted in the testing-room. Messrs. Hodges and Todd have just completed an ammeter 1ft. in diameter for 2,500 amperes, and weighing about 50lb.

Stafford.—It was announced at a meeting of the Town Council last week that the Local Government Board had given formal sanction to the borrowing of £20,000 by the Corporation for a term of 25 years, and to the use of certain land at the gasworks for the purposes of electric lighting. Subsequently the report of the Electric Lighting Committee came up for discussion. The report stated that the committee recently attended on the site of the proposed electric supply station, when the Mayor performed the ceremony of cutting the first sod, and a vote of thanks was passed to him. The committee recommended that the foundations for the new buildings at the electric supply station should be put in by the staff of the department, and that tenders for the erection of the buildings be advertised for. The committee decided, instead of advertising for tenders for the engines, boilers, and dynamos, to obtain the same from certain well-known firms, whose names were submitted to the committee by Mr. Bell. In moving the adoption of the report, Alderman W. H. Peach explained that the latter course was adopted because the committee felt it was important that the work should be done well. Mr. Flamank seconded the motion, which was carried.

London County Council Engineering Staff.—The Establishment Committee have recommended, in connection with the electric lighting branch, that Messrs. H. W. Ridley and A. Champion, whose salaries are now £3. 3s. a week each, be placed on the permanent staff in the second class at the commencing salary of £162. 10s., and that the wages of Messrs. J. J. Thornton, J. Taylor, and T. O. Smith be increased from £2 to £2s. 2s. a week. There are two vacancies in the engineer's department—one caused by the retirement of Mr. R. Elliott, who was in the electrical branch, and the other by the resignation of Mr. E. R. Johnston, junior assistant in the drawing branch. Mr. Wakefield has been transferred to the electrical branch, and to fill his place in the drawing branch the chief engineer has submitted the name of Mr. W. H. Holthum, who is at present employed in a temporary capacity at £4. 4s. in the water branch. The committee recommend that the Council do authorise the employment for 12 months on probation of Mr. W. H. Holthum at a salary of £4. 4s. a week, and that to fill the second vacancy the Council authorise the appointment of an assistant in the third class at a commencing salary of £120, and that an advertisement be issued inviting applications for the position.

Anti-Sulphuric Enamel.—We have received from Messrs. Griffiths Bros. and Co., Macks-road, Bermondsey, a new circular giving particulars of anti-sulphuric enamel. This material—which was first prepared at the suggestion of Messrs. Crompton and Co., Limited, to meet the need of protection for metal and wood work from the destructive action of the fumes and spray in battery-rooms—is evidently fulfilling its purpose satisfactorily. The list of stations given in the circular where it has been employed comprises nearly all those in the United Kingdom in which accumulators are used. Judging from the reports upon the material contained in the circular, there is no longer any need to fear damage to buildings or fittings by the use of storage batteries, as the means of preventing it is simple and inexpensive. It appears that anti-sulphuric enamel is also found to be of use for a variety of purposes in the electrical trade. Being a good insulator, and drying quickly, it is serviceable for coating any articles that require a fine finish, and when applied to metal work it retains a wonderful flexibility. The list of users mentioned in the circular includes the leading firms in Europe, and this speaks for the usefulness of the article. Messrs. Griffiths Bros. and Co. also give a list of shellac varnishes, etc., manufactured especially for the electrical trades.

York.—At a meeting of the Town Council last week Mr. Alderman Milward, replying to Mr. Walker, who had asked for information as to the cost of electric lighting at the new law courts, said the total cost of the gas-engine and fixing the same was £202. 11s. 2d.; dynamo and everything connected with it nil, the committee having made an arrangement with the owners; cost of wiring and all other electric lighting apparatus in the new law courts building, £1,279. 1s. 1d.—total capital expended, £1,481. 12s. 3d. The total cost for one year, 1893, in wages of attendants of engine, etc., was £140. 15s. 8½d.; electrical engineers' repairing, etc., nil; oil, waste, £23. 4s. 11d.; gas for engine, £147. 7s. 6d.; water for engine, £21. 12s. 6d.; new lamps and materials for renewals of electric light apparatus, £29. 2s. 5d.; repairs to engine, dynamo, lamps, etc., £41. 7s. 1½d.—total for repairs, maintenance in wages and repairs, £403. 10s. 2d.; cost of gas lighting for one year, say 1892, in old police office and fire-engine station before business was removed to the law courts, £35. 12s. 8d. Alderman Milward could not say, because there was no separate account, the cost of gas in the Guildhall for that portion of business now provided for at the new law courts. The cost of the gas for the Council-chamber and suite of offices was £55 last year and £47 the year before. The total cost of gas for one year, now substituted by the electric light, was £35. 12s. 8d.

Derry Central Station.—On Tuesday the members of the Derry Corporation attended at the electric light station to inspect the engines and dynamos previous to the contractors proceeding to test the street lamps. Among those who attended were Dr. MacCullagh (mayor), Councillor Magee (chairman of the Lighting Committee), Mr. Collins and Mr. Mittlehausen (of Messrs. Siemens Bros.), Mr. Clamp (of Messrs. Johnson and Phillips), and Mr. David Brown (of Messrs. Alex. Brown and Sons, makers of the engines). General satisfaction was expressed at the way in which the work of the various contractors had been performed. After about an hour spent in examining the works, those present partook of cake and wine in the station on the invitation of the chairman of committee (Councillor Magee), who presided. In a few suitable words the chairman proposed the toast of "Success to the undertaking," coupled with the names of Messrs. Collins, Mittlehausen, and Brown, who severally responded, and expressed their confidence that the light would be a success, Mr. Brown predicting that Derry would soon be the best lighted city in the kingdom. Between eight and nine o'clock Mr. J. Brown started engine No. 1, Mr. Collins switched on the current, and the station was brilliantly illuminated by four lamps of 2,000 c.p. The light was greeted with hearty cheering, and Messrs. Collins and Brown were warmly congratulated by those present on the success attending the experiment. The exhibition was a success, and left no room to doubt that when in a few days the current is turned on to the street lamps the public lighting will not only be a success but afford satisfaction to the citizens.

Electrical Conversazione at Croydon.—At the Whitgift Grammar School, Croydon, on the 7th inst., a lecture on "Electricity" was delivered by Mr. W. Perren Maycock, M.I.E.E. The Mayor (Alderman S. L. Rymer) then presented certificates awarded for electrical knowledge by the Government Department of Science and Art to Mr. H. T. Haws, O.W., who has been elected student of the Institution of Electrical Engineers; a second class advanced certificate to Mr. F. R. McBride, O.W.; and a pass certificate to Messrs. J. M. Donaldson, B. Hopps, R. S. Long, O.W., G. F. Malden, and E. M. Simmins. Subsequently an electrical conversazione and exhibition of apparatus took place. Messrs. Wenham and Waters, engineers, of Croydon and London, exhibited electric incandescent lamps over lecture table, apparatus

Digitized by Google

for domestic use, comprising electroliers, brackets, portable lamps, electric cooking and heating apparatus, etc. The current was supplied from steam-engine and dynamo in the cloisters, and the whole was fitted up under the direction of Mr. G. F. Grimes, O.W. Mr. W. J. Bishop, of George-street, Croydon, showed model dynamos and motors and parts of same, various forms of primary and secondary batteries, signalling apparatus, electric light fittings, transformers and vacuum tubes, measuring instruments, etc. The arc lamp on the top of the tower was lent by Mr. W. E. Wilson, O.W., and was supplied with current from the dynamo fixed by Messrs. Wenham and Waters. A model of new arc lamp, invented and constructed by Mr. W. S. Entwistle, O.W., was on view, and a drawing of a new type of telegraph instrument, designed by Mr. F. Johnston, O.W. Various kinds of telegraph, telephone, and other apparatus were shown as fitted up and made by boys of the electricity class.

The Phonopore.—The Phonopore Company have issued a circular, from which we extract the following: "The company call attention to the further improvements it has lately made in utilising existing telegraph wires and in doubling their carrying capacity. To meet the requirements of several of the railway companies, it has taken up the question of working a single-needle instrument by the phonopore system. This the company has accomplished; and as nearly all telegraphists read by the sound from the needle, it can now offer to railway companies a new sounder, worked by a handle similar to a single-needle instrument, by which an entire circuit can be duplicated. For example, given a single-needle or other circuit, having several stations on it, this new instrument can be attached to the existing wire at any or every station on the circuit, so that each station will have a double means of communication on the same wire, exactly as if there were two separate and distinct circuits. This instrument (or a phonopore telephone for speaking, with a special bell-call on the same wire) can also be attached to the block, bell, or train staff wires without any interference with their working. If the needle instrument is preferred to this new sounder, this can be applied to existing wires, but two wires are required for working the needle. A mixed circuit can be formed of the two systems, sounders and needles. Phonopore telephones can be attached to ordinary telegraph and block wires, and conversation can be carried on distinctly in spite of any ordinary induction. The Phonopore Company now offers the following systems: (1) the improved phonopore telegraph, for working Morse printers and ordinary sounders; (2) the needle phonopore, for working single-needle instruments; (3) the new phonopore sounder, worked by a handle similar to the ordinary single-needle telegraph instrument, or by a Morse key if desired; (4) phonopore telephones, which can be placed on either bell, block, train staff, or ordinary single-needle circuits. On several occasions when a wire has broken or become defective, and the ordinary telegraph in consequence became unworkable, the phonopore telegraph remained undisturbed and continued to work satisfactorily although on the defective wire. The system can be seen at work at the company's offices, Faraday House, Charing Cross-road, London, W.C."

PROVISIONAL PATENTS, 1894.

MARCH 5.

4572. **Improvements in telephonic transmitters.** Charles Adams-Randall, 1, The Avenue, Bedford-park, London.

4575. **Improvements in connection with electrical tramways.** Ernest Edward Vaughton, 12, Cherry-street, Birmingham.

4610. **An improved temperature regulating device for electricity meters.** Ernest Francis Moy, 433, Strand, London.

4635. **Improvements in galvanic batteries.** Hermann Wehmann, 65, Chancery-lane, London.

MARCH 6.

4647. **Improvements in electric lighting by incandescence lamps arranged in series.** Thomas Robert Burrell and Frederic Fowkes, Hawkeshead, Ambleside, Lancs.

4691. **Improvements in apparatus for connecting and disconnecting electrical circuits.** Andreas Peter Lundberg, Gustaf Charles Lundberg, and George Pegg, Bradbury Electrical Works, Bradbury-street, Kingsland, London.

4724. **Improvements in and relating to secondary batteries.** Octavius March, 45, Southampton-buildings, Chancery-lane, London.

MARCH 7.

4788. **Improvements in standard resistance boxes.** Francis Henry Nalder, Herbert Nalder, Charles William Scott Crawley, and Alfred Soames, 16, Red Lion-street, Clerkenwell, London.

4805. **A new or improved method of lighting cycle lamps by means of electricity.** Joseph Muffley Klingelsmith, 22, Glasshouse-street, Regent-street, London.

MARCH 8.

4849. **Improvements in casings, culverts, or means for supporting and protecting electrical conductors.** Gerald St. John Day and Samuel Allmark, 64, Barton-arcade, Manchester.

4904. **Improvements relating to electric lamps.** Robert Hacking, George Brand, Arthur Gibson Howitt, and John Johnstone, 78, Fleet-street, London.

4909. **Improvements in or relating to combined targets and electrical indicating apparatus.** George Henry Collins and Charles Stuart Jones, 46, Lincoln's-inn-fields, London. (Complete specification.)

4910. **Improvements in or relating to the distribution and utilisation of electricity.** William Lloyd Wise, 46, Lincoln's-inn-fields, London. (Edgar Modesse, Belgium.)

4911. **Improvements in or relating to electric supply apparatus, such as alternators and transformers, applicable also to other purposes.** William Morris Mordey, 46, Lincoln's-inn-fields, London.

MARCH 9.

4945. **A combined electricity meter and automatic switch with apparatus for registering the position of an index or pointer.** Ernest George Pink, 10, Seville-place, Dublin.

4969. **Improved device for converting and making oil lamps suitable for electric light.** Somerset Frederick Gough-Calthorpe, 16, Upper Thames-street, London.

4987. **An improvement in arc electric lamps.** Edward Car stensin de Segundo, 28, Southampton-buildings, Chancery-lane, London. (Complete specification.)

4993. **An improvement or improvements in joints for suspending electroliers.** William Whitehouse and Henry Pinnell, 7, Staple-inn, London.

5001. **Improvements in connection with electric fuses and switches.** Albert Essinger and Thomas Harden, 55, Chancery-lane, London.

5002. **Electric lamps.** Horace George Nichols, 11, Argyll-street, Regent-street, London.

5003. **Improvements in regulating electric motors.** James George Willcox Aldridge, 40, Chancery-lane, London.

MARCH 10.

5025. **Improvements in electric rail or tramway systems.** Michael Holroyd Smith, 55, Chancery-lane, London. (Complete specification.)

NOTES.

Christiania.—An electric tramway has just been set in operation.

Derby.—The new School Board offices in Becket-street are to be lighted by electricity.

Civil Engineers.—The annual dinner of the Institution of Civil Engineers took place on Saturday evening.

Oswestry.—The seal of the Council has been attached to the agreement with the Oswestry Electric Light Company.

Madras.—The shareholders of the Madras Electric Tramways Company have appointed a local board, sitting at Madras.

Windsor.—New electric lighting proposals are before the Corporation, and a committee has been appointed to report on them.

New Atlantic Cable.—The Commercial Cable Company expect that their new cable will be completed by the middle of July.

Darwen.—A correspondent asks whether the Corporation intend to light any other building by electricity than the technical school.

Bradford.—The Bradford Gas and Electricity Supply Committee have decided to grant the men in their employ an eight hours' day.

Guildford.—The Town Council have again postponed their decision in regard to the provisional order which is being promoted by a company.

Calcutta.—The Oriental Telephone and Electric Company, Limited, have opened a branch for electric lighting work at 1, Lall Bazar, Calcutta.

Croydon.—The County Council have decided not to expend for the present the £700 already provided for wiring the new municipal buildings.

Buckingham.—A meeting of the Town Council was held on Monday to consider a tender from Messrs. Parr and Gillies for the electric lighting of certain lamps.

Ayr.—The Town Council are ascertaining the number of arc lamps which will be required for lighting the town by electricity, and the number of lamps likely to be needed by householders.

Brighouse.—The Town Council have received an application from the Brighouse Industrial Society for a supply of gas for a gas-engine to be used in lighting their premises with electricity.

Telephony.—The last length of wire in the London to Dover telephone system was fixed on Saturday, and telephonic communication between Dover and the Metropolis was established for the first time.

Sewage Purification.—Mr. Ashmead, the surveyor to the Bristol Sanitary Committee, has been instructed to prepare a report on the different systems of dealing with sewage, including electrical methods.

Maidstone.—The Local Board have resolved not to proceed with their electric lighting scheme, but to negotiate with electricity supply companies with a view to the provisional order being taken over by one of them.

Lecture.—Mr. F. F. Bennett, M.I.E.E., of Messrs. Bennett and Druce, Preston, delivered on the 13th inst. a lecture before the Preston Scientific Society, at the Guildhall, entitled "What is a Board of Trade Unit?"

Extensions at Blackpool.—A Local Government Board enquiry was held last week to examine the advisability of sanctioning a further loan of £24,000 for the purposes of extensions in connection with the electricity works.

Brighton.—A Local Government Board enquiry has been held regarding an application of the Corporation to borrow £32,500 for acquiring the goodwill of the Brighton and Hove Electric Lighting Company, and to make extensions.

Brechin.—At the last gathering of the Town Council, Mr. Jamieson gave notice that at next meeting he would move that the Council apply to the Board of Trade for a provisional order for the introduction of electricity for lighting.

Electric Lighting in Londonderry.—On Saturday evening about two-thirds of the city were lighted by electricity for the first time. The installation consists of 160 2,000-c.p. arc lamps of the Brockie-Pell type. The installation has been carried out by the Corporation.

Walsall.—The Board of Trade having provisionally approved of the electric-lighting scheme for the borough, the town clerk has applied to the Local Government Board to hold an enquiry with regard to the application of the Council for a loan to carry the scheme into effect.

Municipal Electric Lighting.—Under the title of "A Short Practical Treatise on Municipal Electric Lighting," Mr. F. Hastings Medhurst, M.I.E.E., has issued a pamphlet which mainly consists of a reprint of the Electric Lighting Acts, 1882 and 1888, and copies of provisional order and transfer.

The Antwerp Exhibition.—A meeting of the committee of the British section of the Antwerp Exhibition was held a few days ago at the Mansion House. It was decided to make a special effort to obtain the adhesion of the leading agricultural implement makers and electrical engineers.

New Cable.—The new telegraph lines of the Pacific and European Telegraph Company, Limited, between Buenos Ayres and Valparaiso have been set in operation. In conjunction with the cables of the Eastern, Brazilian Submarine, and Western and Brazilian Telegraph Companies, this affords a new direct telegraph route to Chili, Peru, and Bolivia.

Society of Arts.—The council will proceed to consider the award of the Albert Medal for 1894 early in May next, and they therefore invite members of the society to forward to the secretary, on or before April 14, the name of such men of high distinction as they may think worthy of this honour. The medal was struck to reward "distinguished merit for promoting arts, manufactures, or commerce."

The Oldham Central Station.—The principal streets of Oldham were on Thursday of last week for the first time lighted by electricity. The plant is sufficient for simultaneous lighting of 2,500 incandescent lamps of 8 c.p. There are four dynamos, and the total horse-power is 320. The Corporation obtained power to borrow £27,000 to carry out the scheme, which has been superintended by Prof. Kennedy.

Electric Lighting of Breweries.—"It is rather surprising," remarks the *Brewers Journal*, "that electric lighting has not made more headway in English breweries. It has recently been shown to be fatal to the life of bacteria, or at any rate of certain bacterial organisms more potent in power than the majority of those appearing in beer. We have always thought that a well-ventilated fermenting-room, without natural light, but illuminated by electrical means, would be a step in the right direction."

Bolton.—During the past month building operations at the Spa-road electricity works have made rapid progress,

Digitized by Google

and it is hoped that the buildings will be practically completed and the electric current turned on by July. The work of laying down the transformer-chambers, of which there are to be four—one at the junction at Knowsley-street and Deansgate, one in Churchgate, one at the junction of Great Moor-street and Bradshawgate, and another at the Town Hall-square end of Hotel-street—is now being proceeded with.

Royal Institution.—The following are, among others, the lecture arrangements after Easter: Prof. J. A. Fleming, four lectures on "Electric Illumination"; Prof. Dewar, three lectures on "The Solid and Liquid States of Matter"; Captain Abney, three lectures on "Colour Vision" (the Tyndall lectures). The Friday evening meetings will be resumed on April 6, when a discourse will be given by Prof. Victor Horsley on "Destructive Effects of Projectiles"; succeeding discourses will probably be given by Prof. Oliver Lodge, Prof. C. V. Boys, and other gentlemen.

The Abatement of Smoke.—A smoke-abatement experiment is in progress at the City Sawmills, Glasgow. An apparatus invented recently by Colonel Dulier has been applied to one of the boilers, and the results are said to be of an encouraging kind. The object of the appliance is not the consumption of the smoke, but the removal of the soot and sulphurous acid from the gaseous products of combustion. The boiler experimented on is of the Babcock and Wilcox water-tube type, and drives an engine of 220 h.p. Mr. R. R. Tatlock, city analyst, who has on several occasions tested the appliance, reports favourably on it.

The Institution.—An ordinary general meeting of the Institution of Electrical Engineers, will be held on Thursday next, the 29th inst., when the balance-sheet for 1893 will be presented. The discussion will be continued of Mr. Mordey's paper on "Parallel Working Through Long Lines." Papers on the following subjects will be read: (1) "A Universal Shunt-box for Galvanometers," (2) "Transparent Conducting Screens for Electric and Other Apparatus," and (3) "An Astatic Station Voltmeter," by Prof. W. E. Ayrton, F.R.S., past-president, and Mr. T. Mather, associate; and (4) "On the Best Resistance for the Receiving Instrument with a Leaky Telegraph Line," by Prof. W. E. Ayrton, F.R.S., past-president, and Mr. C. S. Whitehead, M.A.

The Scientific Work of Tyndall.—Lord Rayleigh lectured on Friday evening at the Royal Institution on "The Scientific Work of Tyndall." The lecturer said that it was fitting that the memory of Tyndall should be honoured in the place where he had delivered so many brilliant lectures. Tyndall was a personality of exceeding interest. All that the lecturer could hope to do was to bring up to their recollection the more salient points of his work, and to illustrate them, where possible, by experiments of his own devising. There were three distinct parts of Tyndall's work, which Lord Rayleigh then proceeded to pass in review—that relating to heat, especially dark radiation; that relating to sound; and that relating to the behaviour of small particles such as dust. Each of these departments was illustrated by a variety of experiments, and the lecturer was frequently applauded for the success with which they were carried out.

Electricity and Scenic Effects.—We understand that the electrical apparatus made and installed by the Lithanode and General Electric Company, Limited, of 64, Millbank-street, Westminster, S.W., for Mr. Barrett in the Lyceum pantomime of "Cinderella," has been so successful that Mr. Barrett has determined to take the whole arrangement with him to New York. The pantomime, which terminated on Saturday last, is to be reproduced in Abbey's Theatre, in New York, on the 23rd prox. The Lithanode Company have undertaken to send all their apparatus across and instal it for Mr. Barrett. We believe that this is the first time that such a company has ever been taken to America, and it is certainly the first time that electrical apparatus for scenic effects has been transplanted as a whole from this country to New York. It is now generally admitted that the work done by the Lithanode Company at the Lyceum Theatre has been the most successful attempt that has ever been made in this direction.

Electro-Harmonic Society.—The last smoking concert of the season will take place on Friday next, the 30th inst., in the Banquet-room at the St. James's Hall Restaurant, Regent-street, W., commencing at eight o'clock. The following is the programme:—Artistes: The London Glee Singers, Mr. G. Beart, Mr. F. Pinnington, Mr. A. Pinnington, Mr. R. Fisher, Mr. Arthur Thompson, Mr. Arthur Barlow; solo violinist, Mr. T. E. Gatehouse; solo pianist and accompanist, Mr. Alfred E. Izard; silver bells, Mr. R. B. Hopkins; humorous sketches, Mr. Walter Banks. Musical directors: Messrs. T. E. Gatehouse and Alfred E. Izard. (A Blüthner Aliquot concert grand piano will be used.) Programme—Part I.: Madrigal, "This Pleasaunte Monthe of Maie" (Beale), the London Glee Singers; new song, "Arab Love" (C. Deacon), Mr. Arthur Barlow; pianoforte solos (*a*) "La Fileuse," (*b*) "Tambourin" (Raff), Mr. Alfred E. Izard; song, Mr. Arthur Thompson; silver bells, "Intermezzo" ("Cavalleria Rusticana" (Mascagni), Mr. R. B. Hopkins; harmonised melody, "The Banks of Allan Water" (Cantor), the London Glee Singers; violin solo, "Ballade and Polonaise de Concert" (Vieuxtemps), Mr. T. E. Gatehouse; humorous sketch, Mr. Walter Banks. Part II.: Humorous part song, "The Deil's awa' wi' th' Exciseman" (Hedgecock), the London Glee Singers; song, "Biddy Aroo" (air by F. Maitland), Mr. Arthur Barlow; silver bells, "Love's Golden Dream" (L. Lennox), Mr. R. B. Hopkins; song, Mr. Arthur Thompson; humorous part song, "The Goslings" (Dr. J. F. Bridge), the London Glee Singers; violin solo, "Romance in F" (Beethoven), Mr. T. E. Gatehouse; humorous sketch, Mr. Walter Banks.

The Aix-la-Chapelle Central Station.—Messrs. Schuckert and Co., of Nuremberg, were, in May, 1892, instructed by the Town Council of Aix-la-Chapelle to erect an electric light station in a central position in the town, a stipulation being that the firm should run the station on their own account for a certain period of years. Work was commenced in July of the same year, and the station was set in operation by the close of 1892. Mr. F. Uppenborn gives an account of this station in the *Electrotechnische Zeitschrift*, from which we take the following particulars. The buildings are divided into three main sections, which comprise the boiler-house, the machinery-house, and the accumulator-house. There are three boilers, made by Messrs. Jaques Piedboeuf, of Aix-la-Chapelle, and there is room for five in addition. Dry steam is produced, as is necessary for the triple-expansion engines employed. The steam-pipes are made of wrought iron, with the exception of the connections with the boilers and steam-engines, and the bends are of copper. The power plant consists of two vertical triple-expansion engines, made by Mr. G. Kahn, each of which is coupled direct to a Schuckert dynamo. At 150lb. pressure in the high-pressure cylinder and 120 revolutions per minute, the normal output is 350 h.p. The maximum power obtainable is 420 h.p. There is space for two further steam-dynamos, each of 600 h.p. The capacity is from 270 to 280 kilowatts. In the accumulator-house there is employed a battery of Tudor cells of the Hagen Accumu-

Digitized by Google

lator Manufacturing Company's type, and which have a capacity of 1,610 ampere-hours. The network of conductors was at first made for about 14,000 16-c.p. incandescent lamps in use simultaneously. The installation has proved very successful.

Electromagnetic Rotation of the Plane of Polarisation of Acids.—Mr. O. Humburg deals, in the *Zeit. Physikal Chem.*, with the subject of the electromagnetic rotation of the plane of polarisation of some acids and salts in different solvents. He states that in order to ascertain whether a connection exists between the magnetic rotation of an electrolyte and its electrolytic dissociation, a number of fatty acids and of inorganic salts were examined in solution in water and in other solvents. Benzene and toluene were used as solvents for the fatty acids, and methylic alcohol for the salts examined. The rotation of the fatty acids is independent of the solvent, and is the same in aqueous solution, in benzene, and in toluene; this holds even in the case of the chloracetic acids, which must be regarded as strongly dissociated in aqueous solution. The inorganic salts taken were potassium iodide, sodium and barium bromides, and ammonium nitrate. The molecular conductivities of these salts is much smaller when measured in the methylic alcohol solutions than in water, and therefore, as was to be supposed, the dissociation is relatively much smaller in the first case. The rotation, however, remains practically unchanged with change of solvent, showing that it is independent of the dissociation. From the results of these experiments, therefore, it appears that electrolytic dissociation has no appreciable influence on the magnetic rotation. The rotations of chlorine and bromine derivatives of some of the fatty acids and of some hydrocarbons were measured, and from these the atomic rotations of chlorine and bromine were calculated. The numbers obtained were: for chlorine 1·606 in the case of the fatty acid derivatives, and 1·675 from hydrocarbon derivatives; for bromine 3·525 and 3·563 in corresponding cases. The numbers are practically identical in the two series.

Electric Traction on Roads.—A letter has been published in the *Times* referring to "electric road traction." The writer, "C. S.", says: "I have noticed with interest the report of the running of an electrically-propelled parcels van through the streets of the City, but at the same time my interest has been tinged, if not altogether clouded, by surprise as to why so much valuable time, energy, and money should be thrown away in attempting to establish a mode of street locomotion which the Locomotives Act as it at present stands renders a practical absurdity. Being interested in developing a scheme of electric traction for light vans, I wrote to the Commissioner of Police as to the conditions under which such vehicles would be permitted to be used in the Metropolis, and I received in reply the following letter: 'With reference to your letter of the 8th inst., I am directed by the Commissioner of Police of the Metropolis in reply to acquaint you that an electric van is a locomotive within the meaning of the Locomotives Acts, and is subject to the provisions of those Acts as regards not going at a greater speed in a town than two miles an hour, having a man 20 yards in front, and having three men to drive, etc.—C. Bathurst, chief clerk.' The above statement most certainly precludes the employment of electrically-propelled road vehicles for all practical purposes. It is possible, however, that some one of our strong and free legislators may be induced to take this matter up with a view to the alteration of the Locomotives Acts, in so far as their restrictive clauses affect the practical employment of electrical vehicles used for the conveyance of passengers, goods, etc., and thus opening up a fresh branch of industry, benefiting thereby the community at large by reducing the dangers and discomforts attending street locomotion, and by decreasing the number of the unemployed." We are somewhat surprised at the contents of the letter received by "C. S." If we remember rightly, Mr. Radcliffe Ward was informed a few years ago by the Scotland Yard authorities that licenses would be issued for the operation of electrical omnibuses, or, for that matter, electric parcel vans, and that they would not be comprised under the Locomotives Acts. If this assumption is correct, it is difficult to understand the altered state of affairs. Perhaps Mr. Ward will be able to give information on the subject.

The Antwerp Hydro-Electric Installation.—The installation of the works which the Hydro-Electric Company has carried out at Antwerp for the distribution of electricity is based on a system of Prof. François Van Rysselberghe. Our contemporary the *Engineer* states that the system consists, first, in the employment of water under pressure, distributed without appreciable loss, the pressure being obtained either from a natural fall or from steam-pumps distributing water under a pressure of 52½ atmospheres; secondly, in the creation of centres of production or distribution, permitting of the employment of this water under pressure for various industrial purposes, or its use at these centres for the generation of electricity. It is for effecting this transformation of the hydraulic power into electric energy at various stations or centres that the special motors and machinery have been designed by M. Van Rysselberghe, and for the operation of which the pumping machinery, distributing arrangements, and accumulators have been designed. A special hydraulic turbo-electric generator has been designed for use in these district stations. The Rysselberghe motor makes it possible, it is said, to maintain a uniform potential throughout any part of the mains in service within about two volts of the 110 volts used on the circuit. The system then differs from those hitherto employed in that it requires or employs both hydraulic and electrical methods in the distribution of power by electricity, or electricity for lighting purposes, and its author considers that the advantages secured are of great importance. The system provides a public hydraulic power supply system for small or large consumers, and the supply to workpeople working in their own houses is expected to afford a large demand. At all events, it is for the employment of this hydro-electric system that the company already referred to has established works at Antwerp. At present these works contain two horizontal Sulzer compound, receiver steam-engines, with variable expansion gear to the high-pressure cylinder, fixed cut-off to the low. The engines are arranged to work with or without the condensers. By a continuation of the piston-rod of each cylinder, each engine operates a hydraulic pressure pump on the Riedler differential action system. The pumps are strongly connected to the bed-plate of the engines. There are four of these pumps taking their water from a reservoir placed under the floor of the machinery hall. The accumulators are of cast iron, and have each a piston of 500mm. in diameter, or 19 69in., and of 7,000mm., or 23ft. stroke. The steam necessary for the engines is produced by a battery of five boilers, each having two furnaces with Fox's corrugated flues and 16 Galloway tubes; they are loaded to a safety-valve pressure of eight atmospheres, or 120lb. The water, after passing the accumulators, is passed into the distributing pipes, which are of steel, in diameters varying from 300mm. to 131mm., four sizes being used, or from 11·81in. to 5·15in. All the pipes have been tested under pressures varying from 150 to 200 atmospheres, and are provided at intervals with stop valves. The length of distributing pipes will be about 7½ miles, and on this

Digitized by Google

length there will be 10 district central stations for the production of electric current, one of which has been at work in the Place Verte since 1892. Each of these stations will send electric current to a radius of 500 metres, or 1,640ft., and the underground mains will have a length of nearly 10 miles.

The Worcester Central Station.—The scheme for the electric lighting of this town is progressing. It was worked out under the late city surveyor, Mr. S. G. Purchas, by his assistant, Mr. Thomas Caink, A.M.I.C.E., in consultation with Mr. W. H. Preece, F.R.S. Mr. Caink has succeeded Mr. Purchas in office, and as he has all along acted as the electrical engineer, the change will not affect the progress of the work. The installation, it is estimated, will cost the city something over £42,000. The works are about two miles and a half from the city, on the road leading to Upton and Malvern. The station will consist of two blocks of buildings standing at right angles to each other, one stretching across the river, the other with its back to the water and its front on the road, looking towards the city. The building across the river will be 102ft. by 42ft., and will contain the generating machinery. The arches on which it is to stand will be utilised for the turbine-pits, and the building itself will contain the engine and dynamos. The other block, that facing the road, will be the boiler-house. There is water power enough in the course of the year to generate more electricity than the yearly consumption is likely to be. But the supply is not continuous. When the Severn is in flood the water backs up the Teme, and the "fall" upon which the mill power depends is wholly or partially done away with, and during a very dry summer the diminution of the flow from above may cause practically a stoppage. The plant has been laid out on the lines of what is believed to be an economical compromise. Powerful steam-engines must be provided for emergencies, and it has been thought undesirable that these and the capital they represent should be too long unemployed. Therefore, the water power the works will develop will not be quite equal to the possible maximum consumption. With the river in a normal condition, it will be only during this maximum period of the 24 hours' consumption that the water power will require supplementing. The contractors for the machinery and electrical plant are the Brush Electrical Engineering Company. The water power will be utilised by four turbines of the Victor pattern. Something like 350 h.p. will be furnished by these motors, but they are capable of developing 700 h.p. or 800 h.p. As it may be necessary at times to produce the whole of the current by steam power, four boilers equal to 900 h.p. will be put in. They will be water-tube boilers, having an exceptionally large heating surface. Four Falcon vertical compound engines will be used. The generators will be Mordey-Victoria alternators. The boiler-house will accommodate four more boilers, and in the engine and dynamo house space for corresponding extension will be left. The current will be taken underground to the city by mains at a pressure of 2,000 volts, but transformers will be placed at various points bringing the tension in the distributing mains down to 105 volts. The work is being superintended on the spot by Mr. Leonard Wigan, A.M.I.C.E.

The Waterloo and City Electric Railway.—This electric railway, the construction of which is about to be commenced, will be about a mile and a half in length. One terminus will be right under Waterloo Station, and the other will be close to the Mansion House, where there will be subterranean communication with the Central London Electric Railway. There will be no connection of the actual lines, but the booking office at the terminal station of the City and Waterloo line will be in direct communication by subway with the booking office of the Bank Station of the Central London, so that the two lines will afford mutual assistance. On the new railway there will be, as at present arranged, only the two terminal stations. The generating station will be erected to the south of Waterloo, between Aubin-street and Lambeth-marsh. There will also be the shunting ground for the new line, which from this ground will run across the main railway overhead at right angles. The electric line will be only about 35ft. below the platforms of the South-Western, and it is not expected that lifts will be necessary. Communication between the platforms above and those below will be by steps and inclines, and by running one line across at right angles with the other, the underground line is rendered easier of access from any part of the great main line terminus than it would be by any other arrangement. From all the platforms above, steps and inclines will lead directly down to the trains for the City. From this lower station two tubes, 12ft. in diameter will run out northwards, pass under the South-Eastern Charing Cross line into York-road, at the point where it joins the Waterloo-road, and thence into Stamford-street, dropping down towards the river-level with an incline of 1 in 60. The two lines, side by side, will run under Stamford-street as far as Hatfield-street, and then turn north, and for about 150 yards will run under private property, at 55ft. to 60ft. below the street-level. The line will dive under the river a little east of Bull Stairs-alley, at about 160 yards west of Blackfriars Bridge. From this point it will run diagonally across under the embankment at the north-west corner of Blackfriars Bridge, and thence into Queen Victoria-street. Under the middle of the river the rails will be 60ft. below Trinity high-water mark, and there will be a space of 20ft. between the tops of the tunnels and the bed of the river. The railway will at the City terminus be at a depth of about 63ft. below the streets, and here it will communicate with the Central London, which will lie at a depth of 80ft. This line is likely to cost half a million of money. To carry it overhead in the usual way would, it is computed, cost at the very least three millions. This new line will terminate in the City a little to the east of Bucklersbury, in a property just opposite the City Safe Deposit, and having an entrance from Queen Victoria-street and from the Poultry. As regards the rolling-stock of the new line, experience on the City and Southwark has suggested some modifications. It has been found that the existing electric railway would have done much better but for the limited dimensions of its carriages. Their tunnels are only 10ft. or 10ft. 6in. in diameter. The City and Waterloo will make its tunnels 12ft. in diameter and somewhat larger at the curves so as to allow for the turning of the carriages. The carriages will be 9ft. wide, and will each take 50 passengers. Trains will be composed of seven carriages, so that a full train-load will be 350.

Lightship Communication with the Shore.—The Royal Commission on Electrical Communication with Lighthouses and Light-vessels recommended that five light-vessels be immediately connected with the shore by a telegraphic cable—viz., the "Goodwin," at the north end of the sand; the "Kentish Knock," at the Thames entrance; the "Shipwash," off the Suffolk coast; the "Hasborough," off the Norfolk coast; and the "Scarweather," off the northern shore of the Bristol Channel to the southward of Swansea Bay. From the experience gained by the experimental connection of the "Sunk" light-vessel with the shore for a continuous period of 18 months, it has been found

Digitized by Google

that there is no serious difficulty in maintaining the electric connection between a lightship and the shore. The plan adopted in the case of the Sunk Lightship was on the principle that the electric cable should be so led away that it could not get entangled with the mooring chain. To effect this, two mushroom anchors were laid a considerable distance apart, to each of which was attached a sufficient length of chain cable. These lengths of chain were brought together and joined to a large swivel, and from the top of the swivel a single veering chain passed into the lightship through the hawsepipe. This swivel, designed by Mr. F. Bedwell, of the Telegraph Construction and Maintenance Company, had a circular hole through its centre, and a light electric cable from the vessel was carried through this hole and spliced on to the main electric cable, which ran in quite a different direction from that of either of the two arms of mooring chains and anchors. One great necessity appeared to be that the swivel should be always kept above the sea bottom, so as to ensure that the telegraph cable was kept free from contact with the mooring chains. After some experience with this plan, of course involving some failures and fractures, it was ultimately found practicable to keep the electric cable intact without interfering materially with the safe and secure riding of the ship. As she swung round with the tide the light electric cable was passed over by hand, when necessary, to the other side. It is now satisfactory to chronicle the fact that another important lightship has just been put in electric communication with the shore. The Kentish Knock Lightship is in every sense an outside vessel, and is moored in about 12 fathoms at low water. She is 18 miles from the nearest land, and marks the sandbank from which she takes her name in the sea approaches to the River Thames. The nearest land is the North Foreland, and it is from the post office at Kingsgate that the submarine cable is now taken to the lightship. Owing to the much more exposed position of this vessel than that of the "Sunk," it has been necessary to adopt greater precautions in respect of the moorings. Instead of two arms of moorings there are four. The laying of these moorings and fixing the ship to them has been carried out, under the directions of the Elder Brethren of the Trinity House, by the superintendent of the London district, Mr. Hattersley, and Mr. Reading, the master of the Trinity steamer "Vestal." All thing being ready for the reception of the electric cable, the Post Office authorities were informed, and the cable ship "Monarch" was despatched to lay the submarine cable from Kingsgate. Under the personal directions of Captain Lumsden, submarine superintendent of the Post Office, and other officers of the Department, this work was quickly done and the cable brought across the *embouchure* of the Thames to the Kentish Knock. A lighter cable was then reeved through the central hole in the swivel and taken inboard, the other end being spliced on to the main cable, and at 3 p.m. on Wednesday of last week a message was sent through from the lightship to the General Post Office, to the effect that the first of the permanent lightship cables had been successfully laid and communication established.

Polyphase and Continuous Currents at Bockenheim.—In a recent issue of *La Lumière Electrique* a description is given by M. C. Jacquin of the electricity works at Bockenheim, a small town on the northern outskirts of Frankfort-on-the-Maine. The station was carried out by Mr. Lahmeyer on the system he showed at the Frankfort Exhibition. Current is transmitted from the station to the centre of the town at a sufficiently high potential to reduce the cost of the mains, and yet not too high to be detrimental to the good working of motors. With, say, 600 or 1,000 volts, the motors might be connected directly to the high-tension mains, which would run through the principal thoroughfares, and for the lighting of which arc lamps would be run in series from these mains. Next to these would be laid low-tension mains, coupled to the former through special transformers, reducing the pressure from 1,000, or 600, volts to 100. The low-tension mains are connected from a point near the generating station to low-tension dynamos, which are also employed for exciting the high-tension machines. Incandescent lamps, isolated arc lamps, and small motors are run in parallel from the low-tension mains. Since the introduction of polyphase currents and their success at Lauffen, it was clear to Mr. Lahmeyer that his system might be rendered more simple and practical by their use. The commutators on direct-current dynamos working at 1,000 volts, would offer considerable trouble when compared with the simple collectors on polyphase machines. But matters were simplified still further by employing a fixed armature for the latter machines, producing triphase currents at only 80 volts in the station, the pressure being raised to 600 volts on the feeders by similar transformers to those used at Lauffen; these feeders being connected to three-wire ring mains. A sub station contains a special transformer, the primary of which is connected to the three wires of the high-tension mains, the secondary delivering a continuous current at 110 volts into two-wire low-tension mains, to which lamps, motors, or accumulators are connected. The dynamos used for exciting the triphase alternators also feed into the continuous-current mains at a point near the station, and are capable during periods of light load of alone supplying current. The station is at some distance from Bockenheim. The boiler-house measures 7·5 × 17·5 × 12·5 metres, and contains two boilers, with room for a third. Supply water is obtained from the mains. Each boiler has a heating surface of 90 square metres, and can produce 350 kilogrammes of steam per hour at 10 atmospheres pressure, with a consumption of 80 grammes of coal per kilogramme of steam. The machine hall has the same dimensions as the boiler-house. Two independent groups of machines are placed in parallel lines. The switchboard is at the end of the hall, with a raised platform three metres from the floor. There are two horizontal compound Corliss engines, with tandem cylinders, of 250 h.p. each. The field magnets of the triphase alternators are similar to those used on the Lauffen machines—each disc having 24 claws on its periphery, and the two discs when in position give 48 polar surfaces of alternating polarity. The diameter of these field magnets is 2·80 metres, which are worked directly from the engine shaft. The 50-h.p. continuous-current dynamos are belt-driven from the engine flywheels, and run at 600 revolutions per minute. In a chamber under the dynamo-room is placed a condenser, working at 650mm. vacuum. The hot water from the condenser runs in thin streams down a number of boards arranged in steps, and, after being cooled in this way, is used for cooling the condenser; by this simple method it is possible to cool 40,000 litres of water per hour. The triphase alternators are very similar to those used at Lauffen. The fixed armature consists of 144 copper bars 20mm. in diameter, insulated with asbestos, and so connected that they form three distinct circuits, each of 48 coils, these circuits ending in three terminals on the dynamo. The machines are of the simplest construction. Each triphase machine has an output of 150 kilowatts, giving 1,850 amperes at 80 volts. The two four-pole continuous-current dynamos, of the Lahmeyer type, have an output of 36 kilowatts, 30 amperes at 120 volts.

PRACTICAL INSTRUMENTS FOR THE MEASUREMENT OF ELECTRICITY.

BY J. T. NIBLETT AND J. T. KWEN, B.SC.

XVIII.

(Continued from page 231.)

RESISTANCE, *continued.*

Testing Sets.—Before an electric telegraph or telephone cable is put into use, it is usual to subject it to three distinct tests to ascertain its conductor resistance, insulation resistance, and electrostatic capacity. These three properties are usually termed resistance, insulation, and capacity, and it will be observed that they are all specific properties of the conductor itself, and totally independent of whatever current may be flowing in it at any given time. In the case of an ordinary electric lighting circuit, only the first two of these—the conductor and insulation resistances—are measured, and very often the insulation resistance alone is all that it is thought necessary to be ascertained. It is essential, however, that this last value should be accurately determined before the circuit is put into use, to ensure that the insulation is quite sufficient for the purposes of the installation, and to comply with the rules drawn up by the various fire insurance companies for the prevention of fire risks.

It is therefore of the highest importance to the electrical engineer that he should be provided with some convenient device for measuring whichever of these properties he desires; and the apparatus employed must be of sufficient portability to be easily transported from place to place, and also must not be at all likely to get out of order, especially in the case of instruments for measuring light and power circuits. Such a self-contained set of instruments, whether for measuring any one or two or all of these properties, is termed a *testing set.* Testing sets for the measurement of the third property—electrostatic capacity—do not fall to be treated under the present head, but will be dealt with later on when considering instruments for measuring capacity. Testing sets for conductor and insulation resistances are, as a rule, not so elaborate in character as those for capacity, and can mostly be classed as portable testing sets, and it is these more particularly that will be dealt with at present.

For the measurement of the conductor resistance, say, of an electric light or power circuit, which is, as a rule, a very small quantity, the method most frequently adopted is by means of a Wheatstone's bridge arrangement, such as one of those already described. If the two ends of the portion of the circuit being tested are sufficiently near each other, the connections are made between the instrument and the circuit, and the measurement carried out in the usual way. If the ends of the circuit being measured are at such a distance from each other that this cannot be done, as in the case of a telegraph or telephone wire, the earth return is used in the manner illustrated in the last article, page 231, Fig. 43.

As manufacturers usually guarantee the conductivity of their conductors, and as any error in this respect soon makes itself evident, it is usual in ordinary electric light or power installations to either omit this test altogether, or to make it in a very rough way by means of what is known as a lineman's detector, or by some other equally simple method. But as perfect insulation is absolutely essential to the efficient working of any circuit, whether electric light, power, or traction, it is necessary to make the insulation test a very thorough and searching one.

Again, any gradual falling off in the conductivity of an electric light or power circuit, such as might be caused by bad contacts, weakening of imperfect joints, or electrolytic action, soon shows itself at the lamps or motors, but the insulation may go on deteriorating from day to day unnoticed, hence the necessity for repeated insulation tests being made. In the case of central stations, which usually involve an enormous network of wires, daily and even more frequent tests of the insulation are resorted to, and in ordinary installations the fire insurance companies advise that periodic insulation tests should be made and recorded.

As the insulation resistance of a circuit is, or at least ought to be, a very large quantity indeed, it has to be dealt with in an entirely different manner from conductor resistance. According to the rules drawn up by Mr. Musgrave Heaphy for the Phœnix Fire Office, for electric lighting circuits of the low-pressure type—that is, having a potential difference of not more than 500 volts—the whole insulation resistance should not be under the following:

Total number of lamps in installation.	Minimum insulation resistance of complete installation.
25 lamps	500,000 ohms.
50 ,,	250,000 ,,
100 ,,	125,000 ,,
500 ,,	25,000 ,,
1,000 ,,	12,500 ,,

The above figures are for continuous currents; for alternating currents twice the above resistances must be allowed for.

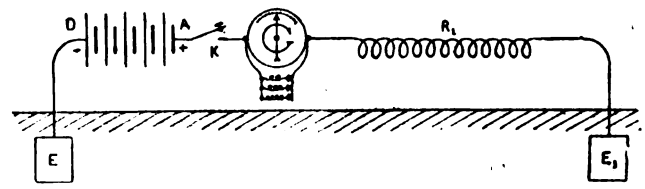

FIG. 44.—Measurement of Insulation Resistance—Known High Resistance in Circuit.

The method ordinarily adopted for the measurement of insulation resistance is a species of simple substitution method, and for this, as has already been shown, a Wheatstone's bridge is really not required. The manner in which this simple substitution method is employed is shown diagrammatically in Figs. 44 and 45, from which it will be seen that, with the exception that the earth is used as part of the circuit, the method is precisely the same as the one already described using the deflections of the galvanometer.

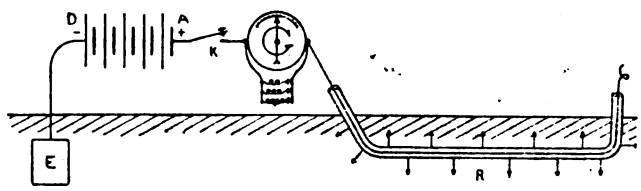

FIG. 45.—Measurement of Insulation Resistance—Insulation substituted for Known Resistance.

The operation consists essentially of two parts: first, determining the constant of the galvanometer with a very high known resistance, R_1, in circuit, Fig. 44; and second, finding the comparative deflection of the galvanometer with R, the insulation of the cable or system, in circuit instead, Fig. 45.

When dealing with such very high resistances, those of the galvanometer and battery being so small in comparison can be altogether neglected without sensible error, and the calculations are much simplified thereby. When the deflection obtained is too great, the galvanometer is shunted so as to bring it within the required limits. The effect of the shunt is to reduce the deflections in the ratio marked on it. Thus, if the deflection of the galvanometer when unshunted is 7·5 divisions, the deflection with the $\frac{1}{10}$ shunt will be 0·75 divisions, that is the same as would be obtained with the galvanometer unshunted and a resistance ten times as great. Thus the same deflection will be obtained with 10,000 ohms and the $\frac{1}{100}$ shunt as with 1,000,000 ohms—that is, one megohm—and the galvanometer unshunted.

From the two operations illustrated in Figs. 44 and 45, the value of the insulation resistance can be obtained as follows:

1. When the galvanometer is not shunted.

Let d_1 be the deflection with R_1 in circuit,
and d ,, ,, R ,,

Then $$R = R_1 \times \frac{d_1}{d}.$$

2. When the galvanometer is shunted.

Let $\frac{1}{s_1}$ be the value of the shunt
when the deflection d_1 is obtained,
and $\frac{1}{s}$ that ,, ,, d ,,

Digitized by Google

Then $$R = R_1 \times \frac{d_1 s_1}{d s}.$$

As the resistance R and R_1 are both extremely high, the battery must be capable of developing a fairly large potential difference in order that a current of measurable dimensions may flow through the circuit. Usually from 40 to 50 volts are found to be sufficient, so that about 30 Leclanché or from 20 to 25 secondary cells will serve for any ordinary insulation test.

ELECTRIC LIGHT AND POWER.

BY ARTHUR F. GUY, ASSOC. MEM. INST. ELECTRICAL ENGINEERS.

(All rights reserved.)

(Continued from page 257.)

THE ELECTROMOTOR.

The function of an electromotor is the inverse of that of a dynamo. The latter is a machine which receives mechanical power and yields electrical power; whereas the former is a machine that receives electrical power and yields mechanical power. A most simple and beautiful illustration showing the broad principle which governs the action of the electromotor was remarked by the writer, who happened to hold an incandescent lamp near the magnets of a dynamo at work in order to examine some defect. The filament of the lamp was drawn on one side so as to bend it, thus showing the pull that magnetism exerts in a conductor carrying a current. Of course, in this case the pull was visible, due to the delicate construction of the filament and the heavy current it was carrying (compared to its sectional area). In dealing with an active copper conductor no visible movement would be observed, although it would be subjected to a magnetic pull just the same.

Any well-constructed dynamo can be run as a motor, provided the same conditions be observed: if the dynamo be a constant-current machine, then it must be run from a constant-current circuit of same value; and if a constant-pressure machine, it must be run from a constant-pressure circuit of same or nearly same pressure as the dynamo is built for.

At the Crystal Palace Electrical Exhibition in 1892, a number of dynamos directly coupled up to steam-engines were converted into electromotors by supplying them with current, and so were made to put the engines into motion, providing an impressive and striking lesson respecting the wonderful adaptability of electricity. Owing to this feature of "reversibility," the construction of a motor is upon lines similar to those of a dynamo; and in most cases it would be difficult to say, without knowing, whether the machine, unmounted, was a dynamo or a motor, although, as a rule, motors are built heavier and with greater mechanical strength of parts than dynamos are.

Efficiency and Speed.—Before touching upon the various types of electromotors and their particular uses, the elementary principles which determine the efficiency and speed of motors will be explained, because the actions of a motor are rather peculiar to those who have no knowledge of this kind of machine.

The germ of the principle is the same as that governing a dynamo. In a dynamo, if a conductor be moved in a magnetic field so as to vary the lines that thread through the coil, an E.M.F. is generated in that coil, and hence a current when the circuit is completed; so that, given two things, movement and a magnetic field, the third, a current of electricity, is produced. In a motor, however, the two things given are a current of electricity and a magnetic field, and the third is produced—namely, movement of the current-carrying conductor; so that if a current of electricity is sent into a conductor or coil placed in a magnetic field, that coil will receive motion, and tend to set itself at right angles to the lines of force, if a number of coils symmetrically arranged in the form of an armature be inserted instead of the single coil, continuous motion would be imparted to the armature, as each coil tends to set itself at right angles to the magnetic field.

When a motor is at work it performs the double function of a dynamo and a motor, because the result of the armature of the motor being in motion induces a counter or back E.M.F. When the motor is standing still there is no back E.M.F., but it increases with the speed; and the faster the motor runs, the greater is the back E.M.F. that is generated. The current that the motor receives must be proportional to the difference between the E.M.F. of supply and the back E.M.F.; hence, upon starting a motor, it will absorb an enormous current, because there is no back E.M.F., and it is necessary to insert a resistance in series with the armature, and hence in series with the field coils when it is series wound, in order to reduce the current to a safe amount, otherwise it would burn up the armature. Putting E for the supply pressure and e for the back pressure generated by the armature of the motor, then the difference is $E - e$, and if R represents the total internal resistance of the motor, then the current that will flow will be $\frac{E-e}{R} = C$. To calculate the efficiency we must compare the electrical power or work put into the machine with the work given out by the machine—

the power absorbed $= C E$;
the power given out $= C e$;
hence the efficiency is $\frac{C e}{C E} = \frac{e}{E}$;

and is measured by the ratio between the pressure supplied and the back pressure generated. It is evident that when the motor is running as fast as it can possibly go, that will be when there is no load on it, and at the same time it will then absorb a minimum of power, because the back E.M.F. will then be at a maximum, and so the current flowing will be a minimum. On the other hand, when the motor is running very slowly, similar to when just starting a tramcar in motion, then it will have a very heavy load on it, and will draw a maximum amount of power, because the back E.M.F. will be almost at a minimum, and consequently the current will be at a maximum. The electromotor then adapts itself in a most fortunate way to its load, and on this account it is particularly suitable for propelling tramcars and the like, as it is just at the starting moment that an exceptionally great amount of power must be developed, in order to overcome the momentum or dead weight of the vehicle, and this is exactly what a motor will do; because when stationary a rush of current takes place, due to there being no back E.M.F., and so provides the necessary starting torque.

The useful work done by a motor was stated to be $C e$; and C was stated to be $\frac{E-e}{R}$, therefore substituting this last expression for C, we have work done $= \frac{e\,(E-e)}{R}$.

It is very easy to calculate the pull on the armature of any motor—only three things are required to be known. These are:

1. The density of the field.
2. The current in the armature.
3. The length of the armature.

Let the density be in lines per square centimetre;
„ „ current be amperes;
„ „ length of the armature be in centimetres;

then pull in dynes = density × current × length ÷ 10; the expression is divided by 10 because the current must be changed to C.G.S., or absolute units, which have a value of ten times the practical unit. Taking an example, suppose the armature of a motor carries 120 amperes, is 60cm. long, and that the field density is 11,000 lines per square centimetre; inserting values we have

$$\text{Pull in dynes} = \frac{11{,}000 \times 120 \times 60}{10} = 7{,}920{,}000.$$

A force of 981 dynes represent a weight of 1 gramme, and 454 grammes make 1lb., hence

$$\text{Pull} = \frac{7{,}920{,}000}{981 \times 454} = 18\text{lb.}$$

Digitized by Google

Putting C for current in amperes;
L for length of armature in centimetres; and
D for density of lines per square centimetre;

we have $$\text{pull in pounds} = \frac{C \times L \times D}{4{\cdot}5 \times 10^6}.$$

Direct-current motors may be divided into two distinct classes, just as dynamos are divided into classes. These two are constant-pressure motors and constant-current motors.

Constant-Pressure Motor.—Motors made to run from a constant pressure source of electric supply can be either shunt or series wound. Shunt motors have several features in distinction to series-wound motors. They will run at very nearly a constant speed, irrespective of what the load may be; and if the field be compounded, then they will run at a perfectly regular speed. In dynamos it is necessary to give the brushes a forward "lead" in proportion to the load or number of lights supplied, but in motors of all classes the opposite holds good—that is, it is necessary to give the brushes a backward "lead"; and the greater the amount of work which a shunt-wound motor does the greater must be this back "lead," so that when there is no load on the machine the brushes will occupy a normal position. It is necessary to have a starting resistance in series with the armature of all motors, whether shunt or series, because, if not, the armature would produce a dead short-circuit. Some motors have their starting switch so arranged that when the machine has got up a fair speed the starting resistance is shifted from the armature coils into the shunt or field coils so as to strengthen the armature current and weaken the field.

In a series-wound motor on a constant-pressure circuit, the pull on the armature bars is in proportion to the amount of current flowing, and since the current is greatest at the starting moment, hence the maximum pull is exerted by the motor at that moment, because there is practically no speed or motion of the motor, and so there can be no back pressure generated. The field of the series motor is not constant like that of a shunt-wound motor. In a shunt motor, the current passing round the field coils is constant, and so at the moment of starting there is a heavy current only in the armature, the strength of the field remaining constant whether at the start or at full speed; but in a series motor, the same current passes through the field coils as passes through the armature. Consequently, when a series motor is started, there is a heavy rush of current for a few seconds through both field and armature coils; hence the statical pull is enormously increased. In addition, a series motor does not run at a constant speed. Owing to these features, it is eminently suitable for traction work, and is almost universally employed for that purpose. Like the shunt motor, it is necessary to insert a starting resistance in the circuit of the motor; none is required in the field coils, because they are in series with the armature. So the starting resistance, the field coils, and the armature are all put in series, making one circuit; then when the motor has got up sufficient speed to generate a back pressure, the starting resistance can be taken out, if requisite. A caution might here be made that the load of a series motor should never be thrown off when the current is on or the motor in circuit, otherwise it will act like an engine without governors: it will increase its speed to a dangerous extent.

Compound-wound motors are not of much use, and are not so safe to run as a plain shunt-wound motor; when they get overloaded the action of the series coil interferes with that of the shunt.

In dealing with motors, very careful distinction must be made between the *maximum efficiency* of a motor and its *maximum work*. It was explained that the faster a motor runs the nearer does the back pressure generated approach to the value of the supply pressure; and since the current flowing is proportional to the difference of these two pressures, it is clear that when the motor is running at its maximum speed there is a minimum of current flowing, and the power absorbed is also a minimum. If it were possible for the motor to run so fast that it would generate a back pressure equal to the supply pressure, then no current would flow, and therefore no power would be absorbed, but the fact of running proves that some small amount of power *must* be absorbed in order to overcome the frictional resistance of the machine; hence the limit of the speed is such that the back pressure is slightly below the supply pressure. The motor is then doing no external work—only running idle—and the efficiency is then at a maximum—perhaps 98 per cent. Taking the other extreme view of the case, let the motor be so overloaded that it cannot move; there will be no back pressure, but a heavy current will flow, limited to a safe amount by resistances. Beyond the heating effect of current, no power is absorbed, and again there is no external work done by the motor, because it is stationary. The efficiency in this case is at a minimum; it receives a large amount of power, absorbed in heating the coils, and gives none out. Hence, when standing still and running at its maximum speed, no useful external work is done. Therefore all external work must be done by the motor at speeds between these two conditions. By experiment it is found that the maximum amount of external work is done by the motor, when the motor runs at such a speed that the current flowing when the motor is stationary is reduced to one-half of its value—that is to say, the maximum work is done when the motor runs at a speed to develop a back pressure equal to one-half that of the supply pressure, so that signifies that when a motor is doing its greatest amount of work, it is working at an efficiency of only 50 per cent., and that the efficiency of a motor varies inversely to the amount of work it does, within certain limits.

(To be continued.)

THE SHEFFIELD ELECTRIC LIGHT AND POWER STATION.

THE STARTING OF THE NEW STATION.

The ceremony of starting the plant in the new central station of the Sheffield Electric Light and Power Company, Limited, took place on Saturday last in the presence of the members of the Corporation and the directors of the company. Alderman Franklin, chairman of the company, presided, and the current was switched on to the underground mains by the mayor (Alderman Foster).

Mr. W. Johnson, the courteous engineer to the company, gave an explanatory statement previous to the current being passed into the distributing circuits. From his remarks we learned that the present electric light station has been built over the site of a pioneer station of arc lighting plant started by Mr. John Tasker in 1885-6. In 1888 the pioneer station was acquired by the late Sheffield Telephone Exchange and Electric Light Company, but at that time the company was extremely busy with telephone work, and was unable to give as much attention to electric lighting as its importance warranted. Still, the possibilities and prospects of incandescent electric lighting were so obviously promising that when it was first endeavoured to deal with alternating-current distribution over scattered areas, one of the earliest made machines was laid down in Sheffield, and the system was given a fair trial with overhead cables. Sudden and unexpected extinction of the lights from various causes frequently took place, but every failure of the light was a distinct and valuable object-lesson. Electrical engineers were being educated day by day, improvements followed in rapid succession, and electric lighting history was written in large characters. The public gave the electric light a hearty welcome, and the company, with every confidence in the alternating-current system and in the electrical and mechanical appliances manufactured by the Brush Electrical Company, laid down such additional plant from time to time as was necessary to meet the growing requirements. In 1892 the company disposed of its telephone business, and changed its name to the Sheffield Electric Light and Power Company, Limited, and with the full sanction of the Corporation of Sheffield at once obtained statutory powers to supply electrical energy within the municipal boundary of Sheffield. These powers made it compulsory upon the company to remove the overhead mains, and to lay down

Digitized by Google

electric light cables as was necessary to supply current within a district in the centre of the town and to give the public a constant supply. It was only by completely remodelling the power station that the company could meet its obligations to the Board of Trade and to the public. Therefore, at the beginning of 1893, the company undertook the work of rebuilding a new and much larger station over the then existing station; the laying of underground mains in the compulsory area; the erection of new boilers in lieu of the Lancashire boilers hitherto in use; the rearrangement of all the engines, machinery, and steam service in the new station; the erection of new machinery; the transfer of the current from the overhead cables to underground cables; and the provision for new consumers. This work had to be done without stopping the supply of current, and it has been accomplished without hitch or serious accident. Hitherto the extension and use of electric light in Sheffield have been restricted only by the inability of the company to supply current, and the completion of the work within the compulsory area is but a step in the direction of enabling the company to greatly extend its operations and to enlarge its borders. To supply current from house to house in the residential districts has always been one of the chief aims of the company, and from those districts has already begun a demand that in its growth will later on tax the capacity of the new premises to meet. Of course, in providing for the future, there must be a limit to the extent of buildings and the provision of floor space for engines and dynamos; but the floor space now available for machinery will enable the company to carry on a large and important work. Mr. J. D. Webster has been the architect for the new station, Messrs. W. and A. Forsdike were the contractors for the buildings, and Messrs. Tasker, Sons, and Co. carried out the steam and water service.

Alderman FRANKLIN, chairman of the company, having welcomed the visitors, the MAYOR addressed the assembly and then switched on the current. Subsequently, the directors of the company entertained the members of the Corporation at dinner at the Masonic Hall. The toast of the evening, "The Sheffield Electric Light and Power Company, Limited," was proposed by Mr. J. D. LEADER and responded to by Alderman FRANKLIN, whilst that of "The Electrical Industries," given by Alderman W. J. CLEGG, was acknowledged by Messrs. RAWORTH, MORDEY, and BINSWANGER.

A public demonstration of cooking and heating by electricity was given at the central station on Monday and Tuesday by the General Electric Company, and on Wednesday evening the staff dinner of the officials and employés of the company took place.

THE BOILER-HOUSE.

Proceeding now to describe the central station, it is noteworthy that ample space is provided for future extensions of the plant. This will be readily understood when it is mentioned that whereas the present capacity of the station is 10,500 incandescent lamps, there is accommodation for further plant capable of bringing the total output up to something like 30,000 lamps. The station is erected in three spans, covering a superficial area of 2,060 yards. The boiler-house, which is arranged under one span, is 112ft. long by 35ft. wide, and occupies a lower level than the roadway. Bunkers have been excavated under the roadway, and into these the coal is shot immediately in front of the boilers. A free supply of water is taken from a large dam supplied by the River Sheaf (Sheaf-field). The boiler-house contains five Babcock and Wilcox boilers, each capable of evaporating 5,000lb. of water per hour. These boilers work at 120lb., and two of them are fitted with automatic stokers. Over the boiler-house is erected a tank holding a reserve of 20,000 gallons of water, and the tank can be supplied from the dam or from the town mains. Duplex wall pumps (one spare) deal with the boiler feed-water, which is passed through a meter in order that the evaporative efficiency of the boilers may be ascertained. The mechanical stokers and the scrapers of the water heater are operated by a small marine engine. The blow-off water from the boilers and all steam-pipe drainage is cooled before being allowed to leave the station.

The arc lighting plant, which has been in use for some years, is arranged at the other end of the boiler-house. This comprises a horizontal compound jet condensing-engine, belted to a countershaft supplying power to three Thomson-Houston arc lighting machines. Each machine will maintain 50 10-ampere lamps in series. This arc lighting plant remains for the present in the position it first occupied, and is the only machinery that has not been disturbed. When necessary, this plant will be transferred to another part of the station, and will be more compactly arranged.

THE ENGINE AND DYNAMO ROOM.

Two spacious and lofty spans, supported in the middle by metal stanchions, have been reserved for the engines and dynamos for incandescent lighting. The plant at present in use occupies only a part of one of these spans, so that there is abundant floor space for future developments. The whole space is light and airy, and the walls are lined with white bricks. At present there are laid down four vertical Brush engines with Mordey alternators. One alternator carries an exciter on its shaft, and there are two separate exciters direct coupled to Brush engines. The alternators comprise two Mordey machines of 100 kilowatts, one of 50 kilowatts and one of 37½ kilowatts, the current being generated at 2,000 volts. The two separate exciters are of the Victoria type, each of 6½ kilowatts. All the engines and dynamos stand on substantial ashlar foundations. Foundations have also been provided for an additional 500-h.p. plant, which is anticipated will immediately be required to meet the coming demand for current. All the alternators are rope-driven.

Duplicate steam-mains have been fixed over the boilers. These mains are 15in. internal diameter, and of wrought steel lap-welded. The pipes leading from the steam-mains to the engines are also of wrought steel with flanges accurately turned, and the pipes have been tested to a pressure of 600lb. per square inch. The bends of these pipes are of copper. Expansion has been suitably provided for, and the steam-mains are drained through well pipes and steam-traps to ensure dry steam. Hopkinson's high-pressure parallel slide valves have been used throughout. All the engines exhaust into a main exhaust trunk, 12in. diameter, to which is attached an independent condenser of the Worthington pumping-engine type, and a steady vacuum is maintained. Any engine may be shut off from the exhaust trunk, and relief valves are provided for the engines to exhaust into the atmosphere if required, or part of the engines can run on the condenser whilst the others are discharging into atmosphere. The discharge water from the condenser falls under the wall pumps in the boiler-house, and is thence forced through the water-heater, which is a Green economiser, into the boilers. All the drain-pipes in the engine-house are laid in concrete channels covered with chequered floor-plates, and the engines and alternators are provided with polished guard-rails. The oil from all the engines is drained into a reservoir, and is then pumped into filters to be used again. A 10-ton travelling crane, made by Messrs. Appleby and Co., is thrown across one of the spans, and brackets have been cast on the metal stanchions supporting the middle span for another crane. In the engine-house there is an office and testing-room, a meter-testing room, storeroom, workshop, messroom, and lavatories; but during the course of future extensions some of these may have to be removed to another portion of the company's land that has not yet been built upon. All the floors are fireproof.

PARALLEL RUNNING.

Such arrangements have been made that only parallel running is possible when more than one machine is in use. All the alternator fields are excited in parallel. Each exciter carries its own automatic switching gear and electrical governor. All the alternators feed into one pair of 'bus mains. Each alternator has its own synchronising pillar. Each synchronising pillar has its own complete switching gear, consisting of one field switch, one synchroniser and switch, and one double-pole main water switch, together with the necessary voltmeter, ammeter, and fuses. The switches are interlocking, and can only be moved in their proper order, thereby rendering accidents from inadvertence

Digitized by Google

on the part of the attendant impossible, and the whole operation necessary to secure synchronism and parallelism is practically reduced to a mechanical process. The pillars are built up of sectional castings. The electrical requirements are excellently provided for.

The current leaving the station is passed through recording apparatus, arranged in a special apartment, for the purpose of obtaining a permanent chart of primary volts, the apparent power sent out of the station at any instant, and the total true watts sent out in any time. These records will, amongst other things, by comparison with the readings of consumers' meters, enable the company to ascertain the amount of loss that may take place in transmission and transformation. The recording-room contains a Thomson primary wattmeter, registering the total output of the station; a Mengarini chart-reading voltmeter, an Ayrton and Mather astatic voltmeter, and three main ammeters, of 20, 150, and 300 amperes respectively, supplied by Messrs. Nalder Bros.

The 'bus mains are taken from the recording-room to the distributing-board, where the various feeder circuits, of which there are four, are controlled by massive aluminium single-pole lever switches. Each pair of feeders has its own ammeter and fuses. A rheostat fixed on the distributing-board controls the excitation, and consequently the primary volts, and here also are terminated the potential leads from the various transformer centres.

The Mains.

The primary circuits are concentric, of the Glover type, insulated with vulcanised rubber, and drawn into 3in. cast-iron pipes. The arc light circuits are concentric, and of paper insulation, lead-covered. The secondary circuits are insulated on Callender's bitumen system, and are laid in iron troughs and filled in with solid bitumen. Seven miles of conductor have been laid in the compulsory area, together with seven miles of spare pipes to meet future demands. The company have also laid down pipes intended for the reception of cables for the residential districts of Ranmoor and Broomhill, as far as the Monolith, so that the distance between there and the suburbs will be quickly covered.

Transformation and Distribution.

The system authorised for use in Sheffield is a high-pressure alternating-current supply partly to converting stations from which a low-pressure supply at constant pressure is given to consumers, and partly, where consumers' premises are scattered, to transformers installed upon consumers' premises. Seven transformer-chambers for reducing the current from 2,000 volts to 100 volts have been sunk below the streets, although there will be nine of them in use in the compulsory area. The transformers, which are of the Mordey type, are joined in parallel between the feeder mains, and the potentials are evenly distributed throughout the secondary network. Hitherto separate transformers have been installed upon consumers' premises, and the removal of those transformers into the chambers has brought about a remarkable decrease in the magnetising current.

The charge made for current is at the rate of 6d. per Board of Trade unit. The company have a showroom for electric light fittings in Church-street for the inspection of intending consumers.

At the present time the company have 8,812 30-watt lamps connected to the mains. The design and general arrangement of the station reflects credit upon all concerned in the matter.

COMPARATIVE VALUE OF CERTAIN WIRING PLANS AND SOME WIRING POINTERS.

BY E. P. ROBERTS.

The statement is frequently made that the arrangement of wires as shown in Fig. 8 gives the same potential at any point of the loop circuit, and that therefore it is the best arrangement, when considered from the standpoint of the lamp. That this is not a fact has, however, been shown, and that it is only true when the cross-section of the wire is made proportional to the current, as in Fig. 9, has also been demonstrated, although many "experts" are not acquainted with the fact. The writer has argued the case with a well-known and really first-class "expert," who, as an installer of apparatus, is one of the best in the country, and who claimed, and still claims, that Fig. 8 not only gives perfect distribution at any load, but takes the least possible copper for a given loss, and that its only disadvantage is that it is not convenient to test out same in case of trouble; also that the "theory" which can obtain the results tabulated below is "off," or the writer is. As the "theory" is Ohm's law, the writer suggested that the only error possible is in the application. The expert stated that he had erected a system of the character shown by Fig. 8, and used two-thirds the copper required by Fig. 6, and a voltmeter showed that his statement was correct, and he did not care for any figures; he went by facts. This controversy furnished much food for thought, and could easily be made the text for an article; it is now only given trusting that it will excite the reader to sufficient interest in the table to work out the results, and then, if he is a believer in the correctness of Ohm's law, he can judge for himself.

The method used for the calculation is the "drop of potential." In each case the same size wire is considered, and the R and C flow being known, the drop calculated. The C for each lamp is taken as constant, which, though not exactly correct, is sufficiently so. If the reader prefer, he can consider the translating devices not as lamps, but of wire of constant R. The error, when lamps are considered, is towards compensation, as increased potential at any point increases C and lamp R decreases, but increased C cuts down potential. This must not be confused with distribution; the action is merely partly compensating for varying R with C, but the increased C exists and the lamp is being strained—the latter is not being compensated.

It may be well to premise the working out of the examples by some general statements which contain truths often lost sight of. All electrical men are now acquainted with Thomson's law as to the economical size of conductors. Many understand how to use it; others, from lack of knowledge of how to determine the variable factors, consider it as of no practical bearing, but the point now desired to elucidate is that Thomson's law is based on the R of the circuit, being based on the energy lost, and that for a given weight of copper the energy wasted for a given amount used depends upon the distribution of the copper, and that by knowledge and careful planning one man can get far better results as to distribution and loss of energy than another, who either does not know or care, or, knowing, will not take the time. Possibly the last man is not paid sufficiently; possibly the more material going in the better for him; possibly he considers it unnecessary labour, because it will never be appreciated.

Case first: The least amount of energy is wasted (commercially speaking) if the loss of potential be proportional to the lineal feet travelled.

If, in Fig. 7, we have four conductors of 10 B. & S. (one ohm per M. feet) leading to a point 500ft. distant and 10 amperes flow, and we connect up, as shown in *a*, *b*, *c* and *d*, we find that the drop and losses are as follows:

	A.		B.		C.		D.	
	P.D.	Watts.	P.D.	Watts.	P.D.	Watts.	P.D.	Watts.
1-2	1·25	—	2·5	—	·83	—	·83	—
2-3	1·25	—	2·5	—	2·50	—	2·50	—
4-5	1·25	—	·88	—	1·25	—	2·50	—
5-6	1·25	—	·88	—	1·25	—	·83	—
1-3	2·50	—	5·	—	3·33	—	3·38	—
4-6	2·50	—	1·66	—	2·5	—	3·38	—
Total	15·	50·	6·66	66·	5·83	58·3	6·66	66·6

Evidently a certain total number of pounds of copper can be used to better advantage in *a* than in *b*, *c*, or *d*, and it is not an equivalent to run one size of wire a certain distance and piece out with another size, even if the total pounds be the same.

For the sake of simplifying calculations, No. 10 wire, and multiples thereof, is used in all the examples. Another way would be to consider the R per millimetre foot, and it is a simpler method for those who are used to using the same.

Digitized by Google

Another case: Fig. 2, *a* and *b*:

	Loss in 1-2 and 4-5.			Loss in 2-3 and 5-6.			Total.	
	Ohms.	C.	P.D.	Watts.	Ohms.	C.	P.D.	Watts.	P.D.	Watts.
A ...	·25	10	2·5	25	·508	5	2·50	12·50	5	37·50
B ...	·33⅓	10	3·3⅓	33⅓	·33⅓	5	1·66⅔	8·30	5	41·66

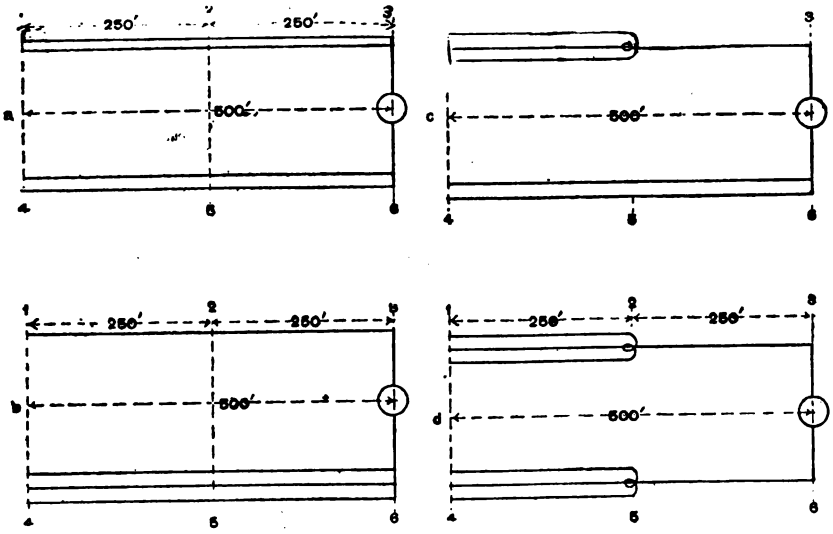

FIG. 1.

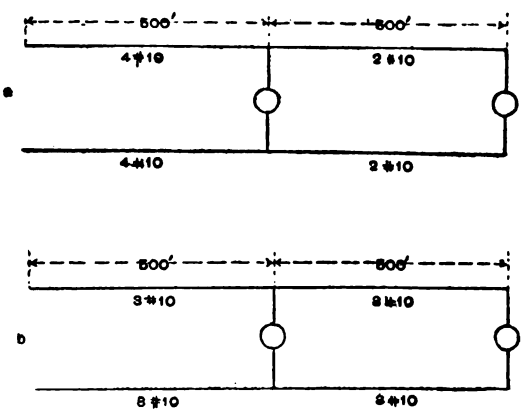

FIG. 2.

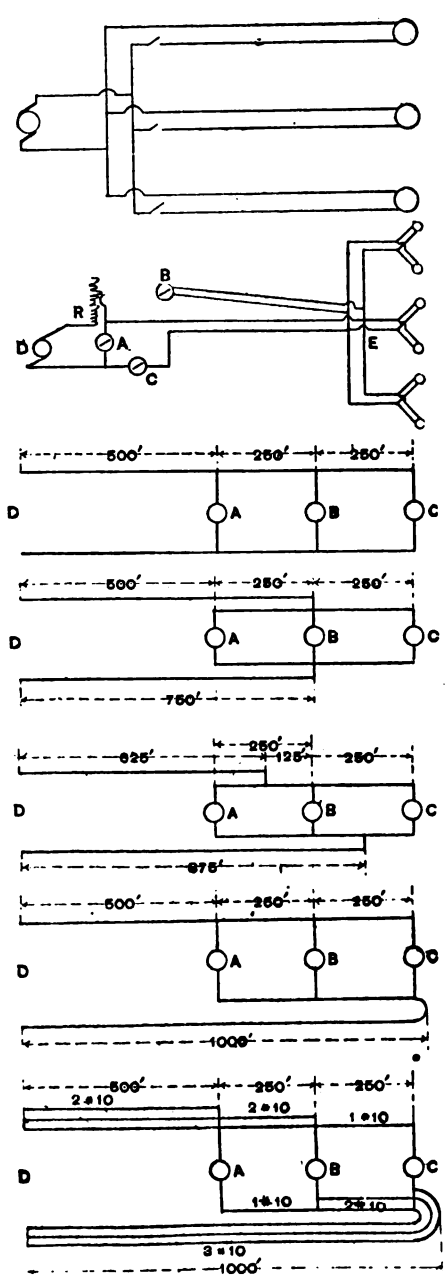


FIGS. 3, 4, 5, 6, 7, 8 AND 9.

Note that although the drop from one end to the other is the same, there is, nevertheless, more energy wasted in *b* than in *a*, but also note that if incandescent lamps be the translating device used, *b* would be better than *a*, because of better regulation. This does not affect the principles as to the least amount of energy lost, but shows that there may be more than one principle to consider

It is generally known that the only way to obtain perfect regulation is to maintain constant P.D. at the dynamo, and to run a separate circuit to each set of devices, all of which must be "on" or "off," Fig. 3. As this is generally impracticable, an effort is made to maintain constant P.D. as near the lamps as possible (see Fig. 4), where D represents a dynamo, R a resistance, so that P.D. at E can be controlled; it may be controlled in other ways; B a voltmeter to indicate P.D. at E; a voltmeter, A, and ammeter, C, may be used, and the P.D. at E kept constant by knowing R from D to E and using Ohm's law. It may, however, be impossible to bring E very near the lamps, or the plant may be an isolated one, in which latter case compound-wound machines are often depended upon for keeping the P.D. at the dynamo proportional to the current, and an effort be made (though probably it is not, and often cannot be made) to have circuits so divided as to all change load in about the same ratio. Whether there be a constant potential point at the dynamo, at some point along the leading wires, or at some lamp, will only vary the conditions and results obtained, but the general deductions obtained from considering the following cases remain true.

Figs. 5, 6, 7, 8, and 9 show different methods of wiring for translating devices, A, B, C. Each device to take 10 amperes.

1. If each is to have the same size wire throughout, consider No. 10, because of convenience, and use two wires for a conductor in Figs. 5, 6, 7, and 8, and in Fig. 9 taper off, as shown, making cross-sections proportional to C.

If potential be kept constant at 100 volts at B and full load, then

	5	6	7	8	9
P.D. at B	100·0	100·0	100·000	100·00	100·0
P.D. at A	105·0	97·5	99·375	101·25	100·0
P.D. at C	97·5	97·5	99·375	101·25	100·0
P.D. at D	120·0	122·5	125·000	127·50	121·5
Total feet wire	4,000·0	5,000·0	5,000·000	5,000·00	6,000·0

If potential be kept constant 100 volts at B, and B be cut down to half-load, A be fully loaded, and C one-quarter loaded, then

	5	6	7	8	9
P.D. at B	100·00	100·00	100·00	100·00	100·00
P.D. at A	101·87	97·50	98·59	100·31	98·44
P.D. at C	99·37	99·37	100·47	101·56	101·25
P.D. at D	110·62	113·12	114·53	115·94	111·56

If potential be kept as before at B, and A be at one-half load, and B at one-quarter load and C at full load, then

	5	6	7	8	9
P.D. at B	100·00	100·00	100·00	100·00	100·00
P.D. at A	103·12	98·75	99·84	100·94	100·31
P.D. at C	97·50	97·50	98·59	99·69	98·44
P.D. at D	111·87	112·12	114·37	115·62	111·25

Many other conditions might be assumed, such as maintaining the P.D. at D constant, and that necessary for full

Digitized by Google

load, which, if D be the feeder end, is often done in central stations; or making P.D. at D proportional to C, which is the case when using an over-compound dynamo, and taking D as the dynamo; but enough has been stated to show that No. 7 is better than No. 8, not only in weight of copper and energy lost, but in regulation at full load, and for most variations under varying loads.

ECONOMY OF INCANDESCENT LAMPS.

BY W. STUART-SMITH.

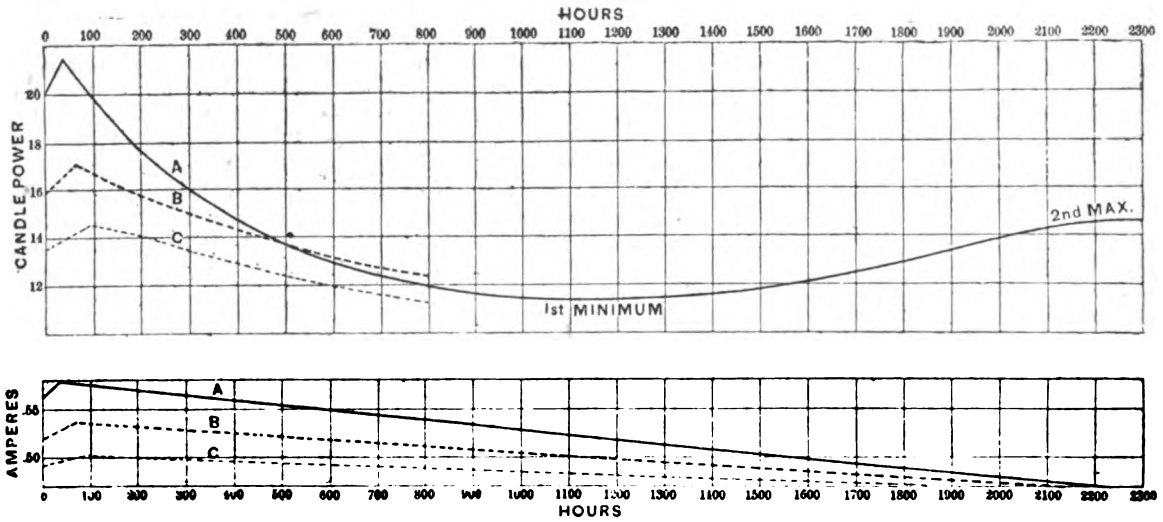
Why does the economy of incandescent lamps fall so rapidly after they have been burning a few hours? Every electrician has asked himself and others this question, and a vast amount of time has been spent and expense incurred trying to find out. The result is that every well-informed electrician will answer "that the filament undergoes a change in structure that seems to decrease its illuminating power." The resistance of the filament and current taken vary but little, while the light-giving powers fall through a wide range. A decrease in the illuminating power would seem to indicate a decreased temperature, which, with a nearly constant current, could only be caused by an increase in the specific heat produced by a structural change, and this explanation is the generally accepted one. It is the purpose of this article to show that such an assumption is entirely unnecessary, and that a very simple and familiar phenomenon is sufficient to account for the fall of efficiency.

After passing through a maximum the current falls slowly and steadily, the curve being very nearly a straight line. This is, no doubt, caused by the resistance increasing as the filament becomes smaller, through vaporisation. As the curve is so nearly a straight line, the current decreases exactly in proportion to the volume of the filament, and the temperature should remain constant, unless there is an increase in the specific heat.

A further examination of the candle-power and efficiency curves will show that the slope becomes less and less with time, and if continued they would probably reach the horizontal, pass through a point of minimum value, and then rise again to another maximum of less value than the first. This last point is not evident from the curves, but, I think, can be shown.

The current curves, if prolonged, will be found to intersect nearly in a point. If this is not accidental, it means that point when the filaments become so attenuated through vaporisation that they become practically of no section. In practice they will break before reaching this point.

In my article on "Blackening of Incandescent Lamp Bulbs" (the *Electrical World*, November 11, 1893) I suggested that the carbon filaments are not homogeneous, and that some portions volatilised more rapidly than others, and if this is true (as seems probable), a microscopic examination of filaments which have burned for some time will show them to have very irregular surfaces, being pitted and scored in every direction. During the early stages of illumination this would not have a deleterious effect, but,



INCANDESCENT LAMP EFFICIENCY CURVES.

Referring to Lieutenant Eyre's article on incandescent lamp economy (the *Electrical World*, January 13, 1894), we see there three sets of curves given, and first it is seen that all three sets of curves rise rapidly for periods varying from 40 to 100 hours, depending upon the original candle-power of the lamps. A maximum is soon reached, after which all the curves fall away.

The increase of the current at once indicates a decreased resistance, and this is probably caused by the filament becoming more dense under the action of the heat, just as a piece of porcelain will contract permanently if raised to a temperature higher than that at which it was fired. Although the filament may not be any hotter than it was at some points in its manufacture, yet the temperature is maintained much longer, and thus may have the effect of a higher temperature maintained for a short time.

The curves are shown as rising in a straight line from the origin to a maximum; it is probable that greater care in plotting would show a concave portion near the origin, followed by a point of contrary flexure, and a convex portion passing through a horizontal at a maximum, then another point of contrary flexure, followed by a curve of large radius. The candle-power curve rises much more rapidly from the origin than the current, due, of course, to the fact that at the higher temperature produced by the extra current a larger percentage of the total energy consists of light-giving rays.

on the contrary, might add to the illuminating power by increasing the virtual surface, just as roughening the surface of a stove is beneficial by increasing the radiating surface. If this is true, then part of the increased illumination near the origin is due to this and part to the increased current, and the effects would be hard to separate. In any case, the effect of pitting would be small and would not prevent the point of maximum light-giving power coinciding with the point of maximum current. After a time, however, a totally different effect will occur. As the pittings and scorings increase in depth a point will be reached when the light emanating from the crests and hollows will be half a wave-length apart, and when this occurs part of the light will be destroyed, with the result that the total illumination will begin to decrease. At first but few points will have the requisite depth for interference, and the diminution of light will be small, but as time goes on the number will greatly increase and interference will take place over the whole surface, and the effect will be greatly diminished illumination, due to the virtual decrease of illuminating surface. The effect will be the same as interference in the case of gratings, opals, Newton's rings, etc. Gratings, opals, etc., produce colour effects, and it may be asked why, if this effect is the same, colours are not also produced. The answer is simple: gratings, etc., are regular, and the results are even distribution of interference with consequent colour effects, but

Digitized by Google

in the case of the filaments, owing to non-homogeneity, the pittings and scorings will be very irregular, and the result will be that colour effects from adjacent portions will be interspersed and the resulting effect will still be white light, though it will have less intensity than originally, on account of a portion of the light having been destroyed. If some colour predominated, it would not show distinctly, but would be diffused throughout the mass of the illumination and give a general tint to the light, and it is well known that the colour does change, becoming more red. Probably it also goes through other tints, but they are less noticeable, as the carbon deposit on the glass tends to absorb them and leave the red, which have the longest waves.

According to this view, the intensity of the illumination of every point of the filament remains the same as before, but the combined effect is less, owing to partial destruction just off the surface. Similar reasoning shows that the carbon is actually heated to the same temperature at all time during its life, but if the radiated heat should be measured it would be found to decrease, owing to interference as before. All this, of course, is independent of the effect of the carbon deposited on the glass. That is a mechanical interference, and has nothing to do with the light-giving power of the filament. It is the filament which is being considered here, and not the lamp as a whole.

It can now be seen why the slope of the curves decrease and approach a horizontal; in fact, why they must reach a minimum value, and then rise again to another maximum, to be followed by a second minimum, etc. As the pits and scores grow there comes a time when a maximum number have the right depth and size to produce a maximum interference, and at this point the virtual surface and consequent illumination will be a minimum, and the candle-power and efficiency curves will both reach a horizontal. Beyond this point interference begins to decrease and the curves begin to rise, but at a less angle than that at which descent was made, because as the filament wears away the current decreases. After a time the pits and scores will reach such a size that the virtual surface will be nearly that of the actual area of the carbon, and the candle power and illuminating curves will again pass through a maximum. This, however, will be less than before, because now the actual surface of the filament is less than originally, on account of the vaporisation which has taken place. Theoretically, there should be a series of waves, similar to sine curves, but having the part below the axis larger than the part above. They would be drawn about an oblique axis, to which they would tend to approach as the filament wore away. After the first wave they would tend to become complex, because the pits would then have considerable size and other pits would form within them and the effects would be superimposed. This recurrence of waves assumes, of course, that the carbons had so much section that they could stand the excessive scoring and pitting without breaking. In practice with lamps of high candle-power and stout carbons, the second maximum might be reached, but probably nothing beyond that, and even this might not be noticed, on account of the blackening of the globes.

High candle-power lamps would feel the effect of this scoring and pitting sooner, because, owing to the greater size and consequent greater want of homogeneity, the pitting and scoring would be more rapid, and thus the more rapid falling off of illumination in high candle-power lamps is accounted for. It is even possible that with such lamps several maxima and minima might occur during the life, though, owing to the pitting within the pits, as above explained, and the consequent superimposed curves, a steady illumination might take place, or, rather, the oblique axis might be reached by the candle-power curve. It could not become permanently horizontal, because the filament wears away and the current falls constantly. However, when the oblique axis was practically reached, the efficiency curve would become a horizontal line or a curve waving slightly above and below a horizontal. When this occurs, the efficiency should be nearly the original value because, though the illumination would be less, it would be practically proportional to the current.

The explanation given accounts for all the eccentricities of filaments, and points out the line to be followed in order to produce lamps that shall maintain high efficiency throughout their life.

The original cause is want of homogeneity, and probably this can never be overcome so long as organic, structural material is used for making filaments. It showed that a non-structural amorphous mass should be used as original material, and this must be chemically produced in such a manner as to be absolutely homogeneous. This being the case, the filaments will wear away evenly without pitting, and though the candle-power will fall steadily as the filament wears away, it will still remain proportional to the current, and the efficiency will retain a constant value equal to the maximum near the origin.

Owing to the fact that experiments are made on lamps as a whole, the fall of efficiency and candle-power observed are the combined effects of the lessened efficiency of the filament and increased absorption by the deposit on the globe. This absorption not only causes the curves to fall to a lower value and gives the oblique axis a greater inclination than it would otherwise have, but it also causes the minimum values of these curves to be reached at a later period, or the minima of the lamp are both lower and later than the minima of the filament.

Also, even if the filament had so much stock that after a time equilibrium in interference might be attained and the efficiency curve of the filament become a horizontal line, the continually increasing deposit would cause the curve for the lamp to slope downward.

FAULTS INCIDENT TO THE PROTECTION OF LIGHTING AND POWER CIRCUITS.

Mr. W. E. Harrington read before the recent meeting of the National Electric Light Association at Washington a paper on the above subject, of which he and Mr. L. Stanley were joint authors, drawing attention to the various causes affecting the reliability of fuses and magnetic cut-outs. The defects in fuses are enumerated as follows:

(1) Lack of uniformity in proportioning and mixing the constituent alloys of the fuse; also in the methods of drawing the wire to a uniform geometric cross-section, and in preparing the fuse for the market. (2) Lack of uniformity, in practice, in the actual placing of the fuse in the following particulars: (*a*) length of fuse for a given service; (*b*) mass of the terminals used; (*c*) position of fuse as to whether it be vertical or horizontal; (*d*) environment, whether it be held in suspension, between terminals, or is allowed to lie along its entire length upon a mass of heat-radiating material, and whether it be open to the air or enclosed in a chamber. (3) Deterioration caused by (*a*) recurring abnormal currents; (*b*) oxidation from various causes; (*c*) disintegration from local voltaic action. 4. Impairment of contact at terminals due to loosening of the clamps from temperature expansions and contractions, or to mechanical or electrical causes. (5) The "Peltier" effect. (6) The abuse of acceptable fusing devices by substituting for the metals designed to be used in them others that are unsuitable. (7) Time element. Practice has demonstrated that fuses rarely, if ever, "blow" in time to accomplish the object for which they are placed in circuit. There is also a wide range of uncertainty as to the constancy of this period of time for any given fuse. (8) Capacity of the ordinary fuse wire to pass current far in excess of its rated blowing capacity for a period of time sufficient, in a majority of cases, to cause damage to some portion of the circuit. The conclusion of the authors is that the fuse-wire cut-out is not only an absolute failure, but actually dangerous.

Magnetic cut-outs are divided into two classes: first, a long-throw knife-blade switch operated to open by a trip actuated by the armature of an electromagnet; and second, a device for preventing or for blowing out the arc formed at the switch jaws by the breaking of the circuit. The principal point of difference in any two magnetic cut-outs of the present day is the methods adopted to overcome the destructive effect of the arc, which are the auxiliary break method and the electro-magnetic blow-out method. Of these the first is criticised on account of the carbon plates or pencils employed, which are not only fragile and quickly destroyed by an abnormal current, but generate a highly conductive gas, which may not only cause damage in the circuit in which it is evolved, but also to neighbouring circuits on the switchboard. Besides, the auxiliary circuit is not competent to carry its proportion of an abnormal current, with the consequence that both the bridge and switch plates may be fused before the circuit is opened. Other defects are pointed out, but the conclusion is reached that, with all of their faults, magnetic cut-outs are superior to fuses.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months	6 months	12 months
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements should be made payable to C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."*

BOUND VOLUMES.

Vol. XII. of new series of "THE ELECTRICAL ENGINEER" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

DIRECT OR ALTERNATE.

There is a never-ending controversy as to the system best adapted for any central station. At the present time the advocates for a high-pressure alternating system generally manage to prove that the system is the one best adapted to that district. We cannot expect business men to trouble much about future years. They have enough to do to obtain orders sufficient to keep works going to-day. It is not, then, to them that we must look for guidance. Shareholders rightly say, sell what you have got and pay as big dividends as possible. If the fashion changes, you must change your productions to meet the new fashions. Well, all this is very good, very true, and very business-like, but there is something more wanted. Reform seldom comes from the inside, and therefore if outside opinion was withdrawn almost all reforms would be long a-coming. We may be wrong in our opinions, but they have often been expressed and not controverted. It is, however, to insist, and insist, and insist upon views not generally adopted till a majority is obtained in their favour. The chief difficulty in constantly harping upon a particular point is that you are taken to be the exponent of that one system only. We have no wish to push direct-current distribution against alternate-current distribution except that the latter seems to be delaying the adoption of electric energy for the production of power. Much has been heard but little has been seen of economical alternate-current motors. With a little perseverance the use of motors should be rapidly extended, and we have no doubt that if direct currents had remained in fashion they would be largely used. It is but a few days ago since the enterprise of the *Pall Mall Gazette* was highly commended by almost every paper in the land. It was long ago said that newspaper information comes by lightning, and it ought to be largely said that they are printed by the aid of electric energy. We are quite sure, however, if the figures are rightly examined, that in a large majority of cases where small power is required, the use of electric motors would conduce to saving. The old saying that "truth will prevail" may be quite true, but the almighty lie prevails for too many years to allow us to come to a conclusion on that subject. The user of power is filled with information concerning steam and gas engines, and is told that one pound of coal burnt in the furnace of the steam-engine will produce so much power, and that so many cubic feet of gas exploded in the cylinder of a gas-engine will produce so much power, and that he can get a horse-power hour for a very small sum of copper coinage. It is not quite possible to determine how much of this he believes, but the fact remains that whether as a small user of power he uses a gas or a steam engine, his power will cost him more than the theoretic figures put before him to charm his order. No doubt a horse-power hour obtained by means of an electric motor will also cost more than the theoretic amount as given in text-books or in papers read before learned societies, but the additional cost will, we believe, be far and away below that incurred with steam or gas.

Digitized by Google

In a very large number of cases where a small steam-engine is used coal is always burning in the furnace, but the power is required but intermittently. In such cases a great advantage is obtained by electricity, in that the current is turned off the motor when the power is not required and turned on when it is required. The power used may, while used, cost more than that from steam or gas, but the bill stops as the machine stops. We do not care to enter into the vexed question of economy under varying loads, for with electricity we get as good economy as with steam or gas, if not better. Allowing, however, that there is no advantage in this, the advantage previously mentioned is enough to warrant our support of motors. Is it possible, then, with the alternate systems now so often used to obtain the development in motors which is so desirable? Nothing need be said of the value of a large power distribution to central stations. That is not the light to view the question. The public must be shown to benefit before it will purchase, no matter the benefit such use and purchase will confer upon the station. Will not some of our towns and some of our consulting engineers think over this matter, and not be guided solely and wholly in their works and designs by the expected demand and extension of demand for light? We think, if experience is needed, the experience of Bradford would be enough to show that "power" distribution must ultimately prove a big factor in central-station work. If the required alternate-current motors are forthcoming, there is little need to trouble about direct or alternate work. Other questions will decide which is preferable.

THE BOARD OF TRADE AND ELECTRIC TRACTION.

It is just a month since we commented in these pages upon the conference then held under the auspices of the Board of Trade for the purpose of discussing and amending the draft rules and regulations prepared by the Board's official staff last autumn as a consequence of the Joint Parliamentary Committee's report on the above subject. No unnecessary delay or waste of time has since been incurred by the Board after once receiving full explanations and comments from those more especially interested; for the complete regulations as finally settled and agreed upon are now published in readiness for insertion in all Acts or Bills relating to such electric lines as may be called street tramways, whilst at the same time draft regulations are issued concerning the electric railroads running underground of a type similar to the City and South London Railway and the numerous other subways proposed to be made in the metropolitan area and elsewhere.

When last commenting upon the subject, we made it clear that great credit was due to the Board of Trade as a Government department for the extremely fair and unbiassed way in which objections to its rules as first drafted were met and accepted. Naturally, therefore, we need say no more on this point, as it was only to be expected that such a line of action would be continued, and that the rules as finally amended would give satisfaction all round, so far as that be possible. Certainly, the electric traction interests have no real ground for objecting to the rules as now made standard, taking also into account the verbal expressions employed by the Board's chief officers as to the feeling of this Department in the matter. This feeling may be characterised as one of friendly interest in electric traction, coupled with a wish to help it forward, rather than hinder its progress by exacting slavish adherence to minute details of the regulations, provided that real efforts are made to comply with their spirit.

Turning to the regulations now set forth in their final shape, it is an easy matter to ascertain the changes effected by united action of the electrical interests by comparing them with the draft rules published last year (see the *Electrical Engineer*, 24th November, 1893); but the operation would prove somewhat tedious, and we can therefore only refer to a few of the most important alterations accepted by the Board. The preliminary definitions remain the same: Rule 1 is modified so as to better explain the term "steady" as applied to the generator, or supply, current. This must now be "without appreciable pulsation." In Rule 2, the words "insulated throughout its length" are struck out as referring to the line wire, thereby avoiding the troublesome question as to whether such insulation is "from earth" or of an absolute type implying a covered wire. Rule 3 allows uninsulated returns to be within three feet of the rails, not necessarily between them; and also permits their use generally when of sufficient sectional area. In Rule 4 a similar latitude of three feet is allowed for uninsulated return conductors to be connected to the rails.

Rule 5 is materially qualified as regards making connections with earth from uninsulated returns: the size of water-pipe to which connection is permissible being reduced from four to three inches, but the consent of owner and water company is essential, together with metallic connection to earth-plates. Rule 6 was very fruitful of discussion at the Board of Trade conference, and has been considerably altered; the chief point is a virtual increase of the ten amperes limit of earth current to two amperes per mile of single line, or 5 per cent. of the total current output. On Rule 7 the Board has adopted in its entirety the suggested amendment of the London Chamber of Commerce Traction Committee, much to the advantage of the traction interests.

The next item to notice is in Rule 10, where the limit of leakage current is raised from one-tenth to one-half ampere per mile, and twenty-four hours are given to localise any fault before stopping traffic. This, of course, does not apply to conduit lines. Rule 12—rather a tiresome one, allowing aggrieved owners of adjacent wires to protect themselves by anti-induction appliances in the tramway wires—is, we are glad to see, qualified by appeal to the Board. The real bone of contention lay in Rule 14, which has had all the sting taken out of it, though a great deal of uncertainty may yet be found lurking within the expression "reasonable precautions." Nothing of great importance requires notice in the other rules,

Digitized by Google

and taking them all in all as they stand, the traction interests are to be heartily congratulated on the success of the efforts made by the Institution of Electrical Engineers, the London Chamber of Commerce Traction Committee, and others to secure their adoption as amended.

As a consequence of this preliminary clearance of the ground, we confidently hope and expect to chronicle in the early future some real solid progress in electric traction. The conditions now laid down are not by any means too onerous to prevent success being achieved under proper supervision and maintenance, whilst they are certainly of such a character as must tend to keep down reckless schemes. Although, therefore, an admirable opening is to be found in this direction for the profitable employment of money, good results will only be obtained by the exercise of every possible care such as an excellent management would consider essential. A wide field is now open—almost untouched—with supervision of an indulgent nature to the well-behaved. We shall be greatly surprised if there are not many eager to avail themselves of the opportunity.

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

INVENTORS AND PATENTEES.

SIR,—Mr. Fitz-Gerald's letter most opportunely negatived to some extent your leader headed "The Guileful Patentee." I would suggest you amend its title, and call it "The Innocent Financier." I, for one, and I know many other electrical engineers, have a great respect for your paper, and the fair-minded way in which it has represented the electrical industry, but your leader is distinctly retrograde. You have evidently taken a lesson from one of your contemporaries, and I venture to say a bad one.

You write with strong disapproval of the men who 12 or 14 years ago were the pioneers of the present electric light enterprise, the majority of whom have unfortunately failed in reaping any benefit for much labour and money expended in discovering, experimenting, and patenting what at the time were new and necessarily untried inventions; and you seek to protect the guileless capitalists, and the would-be financial agents, and company promoters, whose sole desire is to accumulate wealth speedily at the expense of other people's brains and money.

Your leader will have the effect of discourging inventors—*i.e.*, the men who create new industries by which and from which new business germinates—the men to whom this country is indebted for its prosperity, and the perfection of machinery and apparatus which alone enables our manufacturers to hold their own in competition with other countries.

If a few of such men as Wheatstone, Hughes, Wilde, and, in later times, Edison, Siemens, Swan, and others, have reaped some advantages, that does not in any way compensate the enormous majority of inventors who have lost their all in ambitious efforts and honest endeavours to rise above their surroundings. I could name a score of such men, all well known in the electrical world. Some, like poor Lucien Gaulard, are driven to despair and suicide—he asked for bread, but ye gave him a stone. Gaulard's letters and the story of his struggle is pitiful reading.

Your opinion of the readiness of the level-headed men who manage firms and companies to take up new inventions is entirely fallacious: they do just what seems to them best to serve their own ends, and more often than not suppress any new invention, however meritorious, which might interfere with their own tried patents and trade monopolies; and, as I shall point out, the patent laws enable them to do so, and I am bound to say, in justice to them, are a cause of their so doing.

I have been under the necessity of searching through, I may say, some thousands of patents, and I say advisedly that the majority of patents are earnest, painstaking efforts to secure perfection, and as such should not be grudged any reward they may, if lucky, receive. On the other hand, my own experience of capitalists and financial agents is that they do not require championing or safeguarding; they are well able, and indeed always do protect themselves, and take the lion's share of any profit that may accrue from an invention. This is undeniable.

Now, Sir, I come to the real issue, and the reason why there are dishonest patentees (not inventors). I unhesitatingly say it is due only and solely to the existing patent laws of this country. Say there is a new departure, or a discovery that may be brought into practical use if only inventors or improvers can find their way to do so. There are scores of men, born with inventive and fertile brains, who set themselves to seek a way—a few succeed, or partly succeed—and to secure their ideas take out patents. Now comes the crux. What does the Patent Office give them for their fees—a right? No. A monopoly? No. They pay the fees for a vain protection, not tenable or maintainable against money. The patent laws of this country gives no right or security to the invention of a poor man; a patent is of no value until it has been proved, often at an immense expense, in a court of law. There is no search, no investigation into the novelty or priority of his invention, and, unfortunately, no refusal by the Patent Office authorities; they take the fees, and only give in return the doubtful advantage of publicity. If the invention becomes of note, it is more often than not assailed, with the result that the patentee has either to give up his rights or make sacrificing terms with the greedy capitalist or financier. On the other hand, the absence of all check, search, and investigation by the patent authorities enables the dishonest patentee to secure any patent and to trade upon the empty title it gives, and so to dupe the people of their money; in fact, the absence of all investigation makes it easy for rogues to create a fictitious patent and palm it off as a novelty. In the course of my searches I have actually found patents in great part copied, word for word, and reproduced and repatented years after the date of the original patent by others (I need only mention such patents as fluids for use in batteries, etc.), and it is a fact there is no check, excepting only the nine months' previous record, upon patents. That is the real cause of the dishonesty and the origin of the "guileful patentee." I say that the present patent laws which will grant any man a patent provided the fees are paid is a monstrous injustice, and a curse and a cause of crime. It is dishonest, inasmuch as it gives no tangible right to the honest inventor in return for his fees; it is dishonest, as it indirectly incites and holds out the strongest temptation to dishonesty in patent-mongering, and it thus gives a premium to dishonest patentees.

If the patent authorities were empowered by statute to make a thorough search and examination into the priority and novelty of inventions before they grant a patent, as is done in the U.S. of America and Germany, then, I venture to say, there would be an end of the dishonest patentee and his bogus patents, and the patent granted to an inventor would be a fair return for his brains and money and the fees charged by the Patent Office. Such a patent would be a real protection to him, and an inducement to the level-headed managers of firms and companies to entertain without the expensive search and investigation now absolutely necessary; thus the real inventor would stand a fair chance of reward, whilst the rogue would be shut out.

Inventors, as a class, in my opinion, deserve your warmest support, and I ask, what I am sure you will give them, a fair discrimination in your criticism. It is hard enough for honest and genuine inventors to make even fair terms with capitalists, etc., and they are entitled to look to their own trade journals for at least fair play.—Yours, etc.,

HENRY F. JOEL.

London, March 21, 1894.

IMPORTANCE OF COMPLETE METALLIC CIRCUIT FOR ELECTRIC RAILWAYS.*

BY J. H. VAIL.

In the early days of electric railway construction two distinctly different systems were devised and competed for public favour, the one being the overhead double-trolley system, affording a complete metallic circuit for the outgoing and return of all the electric current required to move the motor cars, and the other being the single-trolley system, using the track and earth as a common conductor for one side of the circuit, and the trolley wire and parallel mains for the opposite side. The double-trolley system was found impracticable of operation in many of its details, and the single trolley, because of its simplicity and convenience, has made rapid advances in public favour. The single-trolley system has depended largely upon the earth and buried pipe systems for completing the circuit.

Many devices for making the track and earth combined a more complete and low-resistance circuit have been resorted to—such as burying copper or iron plates, old rails or old car wheels, and connecting the same to the track; or, at frequent intervals, driving iron rods down in the earth and connecting by wires to the track; or by making actual connection with wire from tracks to gas and water pipe systems. Also, for supposed reinforcement of the track, we have used a bare wire of iron or copper, buried in the earth, laid parallel to the track, and connected at frequent intervals; also the supposed electrical connection of rails at joints by bond wires of iron or copper, only having a small fractional part of the capacity of the rail as a conductor. In the early days of electric railway construction it was assumed by experts that the earth and the buried pipe systems would, when combined, form an ample return for the electric current. At that age of the art experts did not fully appreciate the immense quantities of current that would be carried, and therefore did not foresee that these currents when disseminated would produce the serious results that have been caused by electrolytic action on systems of pipes buried in the earth and owned by other companies. Frequent tests prove that the earth itself cannot afford the free path for the current that was anticipated. Earth conductivity has been over-estimated. Iron and lead pipes, being better conductors than earth, must of necessity carry the current, if no superior path is offered by the method of construction. The natural moisture of the earth hastens the destructive electrolytic action of the current on these pipes. In some soils electrolysis is more rapid than in others. The rapidity of action depends upon the chemical constituents of the soil.

It has been found that illuminating gas leakage held in such soils as underlie the cities of New York, Brooklyn, Boston, Philadelphia, and elsewhere, hastens electrolytic action. To prove that the methods of work mentioned are still in vogue, I quote the following section from specifications recently sent out from the office of a prominent electric railway company:

"*Bonds and Supplementary Wire.*—Each rail shall be connected together by two bonds, made of No. 4 galvanised iron wire (Roebling gauge), to each end of which shall be brazed two $\frac{9}{16}$in. Norway iron rivets. Both of the bonds shall be separately connected with a No. 0 galvanised iron supplementary wire, by means of No. 4 galvanised iron wire connections, which shall receive at least four turns around both the bonds and supplementary wire and be thoroughly soldered to the same. Ground-plates shall be placed about 1,000ft. apart. They shall be buried not less than 8ft. in the ground, preferably in damp places, and two No. 0 galvanised iron wires shall be brazed to the ground-plate, and connected one to each supplementary wire in each track, by thorough wrapping and soldering. The ground-plates shall be of galvanised sheet iron, 2ft. square and $\frac{1}{8}$in. thick, bent around in the form of a spiral."

It is evident that electricians had then perfect faith in the earth as a conducting medium. Evidence had not been produced that Mother Earth was incapable of carrying the enormous quantities of current required; neither had an opportunity been afforded to demonstrate her capacity. That some still have faith in the earth's ability in this direction is attested by above specifications and other constructions being executed at this date.

Having briefly reviewed the practice for the past few years, let us now have a look at the resultant effects. In cities provided with electric railways destructive electrolytic corrosion is now acting upon gas and water pipes, and will inevitably produce serious impairment of all such underground pipe systems within a brief period, unless prompt measures are taken to prevent further damage. Within the past year strong evidence of damaging electrolytic action has been produced. Simply for the sake of fixing the evidence on your memory, I will mention only seven instances of electrolytic action of railway currents on gas and water pipes in different cities.

1. A section of iron water-pipe shows complete perforation, caused in four weeks' time. The lead covering of telephone cables also show serious damage. A large number of additional items will be found in the report to Board of Electric Subways for 1893.

2. A plumber in a city in Pennsylvania was repairing a water-pipe in a house, and on breaking joint, an electric arc formed across the separating ends of the pipe. This house was not in the direct path of the railway circuit. Investigation followed, proving beyond question the insufficient electric conductivity of the track system; also that the earth did not afford a good return though the tracks were well grounded. It was found that the railway current was travelling all pipe systems in its effort to complete the circuit to the dynamos in the power station. Actual tests were here made by an expert, using standard instruments. From 135 readings of the ampere-meter it was found that the feed-water pipes leading in the station carried an average current of 93 amperes. Further careful test proved that with 23 cars in operation on the system, 40 per cent. of the total current was carried on the underground pipe systems.

3. December 15, 1893, a fire occurred in the basement of James Sutherland's house. After being extinguished, investigations showed that the current of the electric railway system had been carried along the iron water-pipe, and that probably by vibration causing the pipe to come in contact an arc formed between the water-pipe and gas-pipe, burning a hole through the gas-pipe and thus set fire to the gas. The house was saved by prompt action.

4. Tests show the electric railway current present on the water-pipes. In the generating station the fireman gets a shock when he opens the furnace doors of his boiler with the bare hand.

5. A test recently made by an expert engineer developed the fact of a loss of 24 per cent. on the system, and a difference of 25 volts potential between parallel tracks opposite the power station.

6. Prof. Barrett, in an exhaustive report to the Mayor of Chicago, states that "this destructive action is not alone confined to the lead covering of telephone cables, but is acting on gas and water pipes and almost all buried metalwork," and that it can only be a question of time when more disastrous results will manifest themselves.

As further and substantial evidence, I here exhibit for actual examination a section of 6in. water-main from city No. 7. This pipe has been entirely corroded through by the action of the electric current of the street railway system, which was constructed under my direction about four years ago. This effect was produced in about 2½ years; another section was rendered useless in six months. Abundance of additional and substantial evidence can be produced. These serve to prove the case, which can no longer be successfully denied nor assigned to other causes.

It has been stated that in an electric railway system where a connection has been made to water-pipes, the pipes have carried as much as 28 per cent. of the total current. Instances are known where as much as 40 per cent. is carried on the pipe systems. It is the opinion of the writer that any gas or water pipe system used as a carrier of electric currents will not only be corroded through the body of the pipes, but will surely in due time show defects at joints, as here will occur higher resistance than in any other portions of

* Paper read before the National Electric Light Association, Washington, February 27, 1894.

Digitized by Google

the pipe system. It has been proven by test that the electrolytic action of even five amperes of current on an iron pipe is considerable, and that much damage will result in one year. The rapidity of action depends upon character of soil, amount of moisture, and quantity of current; the destructive action is constant and sure.

I do not wish to create unnecessary alarm, but there can be no question that a grave danger confronts us, and must be surmounted. Instances are numerous proving that the electric railway current is present on the gas and water pipes in buildings contiguous to electric railway lines. Even those of us who are familiar with handling the electric current hesitate to draw a combination of electricity with our gas or water. We know that the gas and water pipes entering our houses may be charged with such a current, and that it only remains for the circuit to be completed by a possible accident through our bodies, or the occurrence of a fire by automatic action between vibrating pipes. City engineers, water companies, and gas companies are placing the responsibility upon the railway companies for the damage caused on pipes by electrolysis.

Any system using ground-plates ground-rods, or substitutes therefor, or bare return track wire buried in the earth, is constructed primarily to utilise the earth as return circuit; when the earth does not afford good return, the current is sure to follow the water-pipes, gas-pipes, or other buried conductors offering the path of least resistance. We now see that these prove to have been only make shift methods to reduce the cost of construction. We find that the evidence thus produced and the troubles constantly occurring in existing street-railway systems are sufficient to show that all methods of grounding the track circuit or connecting to pipe systems should be entirely discontinued; it therefore becomes of vital importance to so construct the electrical railway system as to avoid all electrolytic action on buried systems of metal work that are the property of other concerns.

Having produced the evidence and established the case, let us briefly analyse the matter and ascertain the reason for these results. The whole case may be stated in the single sentence, that the electric current must under natural laws follow the path of least resistance. What was intended to be good has proved to be defective electrical work executed in connection with track systems, has not given to that side of the system a perfect path for the travel of the current, the conductivity of the rail circuit being impaired to such an extent that the electric current must force itself through the earth or through metal pipe lines buried therein.

We must here diverge for a moment to show how the incandescent electric light system operated in multiple arc compares with the railway system. An electric railway system may in some degree be compared with a system of electrical distribution for incandescent lighting, the groups of lamps in buildings connected in multiple arc, comparing with each car and its motors demanding current. The systems otherwise differ in important particulars; the load on the electric light system is not subject to such violent fluctuations as on the electric railway, where the instantaneous demands for current and its equally prompt release must be controlled. The current required for the car is a moving load as the car progresses on its route; this and all other differences of conditions must be duly considered when laying out the system of distribution. With the electric lighting system, the current for consumption is derived from the mains, the equalisation of pressure is maintained through the feeders: the mains are of equal capacity on either side of the system.

With the electric railway the track forms one side of the consumption circuit, and must be so treated in regard to distribution of current as to utilise its carrying capacity equally with the other side, and thus equalise the delivery of current. The electric conductors composing a system of distribution for electric railways should be so thoroughly well proportioned as to show the minimum variation of pressure throughout the system, even when the entire number of cars are in operation. This equality of pressure is an important requisite for the economical working of the motors. The writer has tested electric railway systems operating with a station pressure of from 500 to 550 volts, and showing only 300 to 325 volts on various divisions of the system. Here is a direct loss between dynamos and motor car of over 40 per cent. Is it, therefore, any wonder that some roads report extraordinary coal consumption? Such loss in pressure indicates radical faults in the original planning of the system and the distribution of copper. When operating under low voltage, the motors demand an increased quantity of current above what should be the normal supply, thus augmenting the heating effect in the armatures and fields, the efficiency of the motors being reduced in corresponding ratio.

A further examination into other features of construction requires some consideration of the bonding of rail joints. The existing methods of utilising railway tracks for conducting large quantities of current are faulty in at least three particulars: (1) Restricted conductivity at joint, due to insufficiency of the rail bonds. (2) Neglecting to properly utilise the track as a conducting medium. (3) Failure to provide a complete circuit of low resistance.

For electrical purposes we cannot regard the joint plates and bolts as of any permanent value; the contact is electrically imperfect, the metal surfaces oxidised and under constant movement, due to passing cars pounding the rail joints. The rail sections are in many systems of ample conductivity to carry more than the requisite current provided they are perfectly bonded and properly connected by feeders with the dynamos. We must, therefore, bond the rail joint in such a mechanical manner as to maintain perfect electrical contact, and with sufficient metal to restore at the joint nearly the full conductivity as of the rail itself; and at the same time to give the existing joint plates their present freedom of motion.

It has been found that a system of track with faulty rail bonds will give a shock to animals and, possibly, to human beings, should the same be brought into actual contact in such a manner as to complete through them the broken circuit. It will be readily understood how difficult it is to maintain proper inspection of the electric bonding where the bonds are covered up by the street pavement. Under such conditions the ground circuit and the bonding escape inspection until excessive coal consumption, loss of current, and other troubles force themselves upon the attention of the street railway management.

Observation proves that a faulty rail bond will show its location in winter by heating, due to high resistance, and if snow be present on the ground around the joints the snow is partially melted, thus indicating location of fault.

Let us turn our attention for a few moments to the question of the conductivity of the rails.

For the purpose of comparison, we will assume that iron has six times the resistance of copper. (The actual proportion being 1 to 5·63.)

CARRYING CAPACITY OF RAILS (prepared by G. F. Sandt, E.E.)

—	56lb. rail.		70lb. rail.	
	One rail.	Single track of two rails.	One rail.	Single track of two rails.
Area in square inches	5·4874	10·9748	6·8593	13·7186
Equal in area to circle whose diameter is in inches	2·642	3·735	2·95	5·90
Equivalent in cir. mils to	6,980,000	13,960,000	8,702,500	17,405,000
Resistance per foot B.A. units	·00000845	·00000422	·00000679	·00000339
Equivalent to copper resistance in cir. mils	1,175,000	2,350,000	1,463,000	2,926,000
Equivalent to copper rod whose diameter is	1·13	1·533	1·21	1·71
Safe carrying capacity of iron reckoned at one-third that of copper in amperes	390	780	488	976

Note.—In the above statement the areas of rails have been determined by use of the planimeter. The ampere capacity of iron has been based upon the most reliable data obtainable. The author believes that the figures submitted are sufficient for comparisons, but cannot guarantee their absolute accuracy.

3	43
2	50
1	58
0	67
00	77
000	90
0000	105
½in.	117
¾in.	203
1in.	302

Data furnished by A. E. Kennelly, February 12, 1894.

These figures serve to show how utterly absurd it is to bond a track of 70lb. T rails with iron rail bonds No. 4 or No. 0 in size, and to pretend to reinforce their conductivity with a No. 0 iron or even a No. 0 copper wire. It is like laying a 12in. water-main and then putting a ½in. pipe alongside to help it out. The No. 0 B.W.G. copper wire has a resistance of over 20 times the single track of 56lb. T rails per foot and the No. 0 B.W.G. iron wire over 112 times the resistance per foot of the same track. How, then, can either of these be of any adequate assistance for conducting current?

The following lines indicate the small value of a supplementary wire of either iron or copper when compared with the conductive capacity of a properly bonded single track of 56lb. rails. They represent areas in accurate proportion for comparison. Fig. 1 shows the diameter of a circle indicating the single track of 56lb. rails. Fig. 2 represents the iron reduced to resistance of copper. Fig. 3 shows the No. 1-0 supplementary copper wire and Fig. 4 the No. 1-0 supplementary iron wire reduced to resistance of copper.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

The writer knows personally of several instances where the copper supplementary wire has absolutely disappeared. The writer believes that 99 per cent. of the money expended for so-called supplementary wire is absolutely thrown away. The same money expended in other directions will give more adequate return.

Does not this show conclusively that we should give our attention to the more perfect bonding of the rail joints, and also to apply track feeders in such a manner as to fully utilise the conductivity of the track and thereby make it fulfil the service of which it is capable when properly treated? We are in error when the track system is named as a return circuit. The track system of all electric railways should really be the positive side or outgoing circuit. The writer fully explained this in a brief article in the *Street Railway Journal* about a year ago. It will be readily understood that as the current travels from positive to negative, therefore any arc which occurs between the trolley wheel and the trolley wire will carry metal from the trolley wheel and deposit the same on the trolley wire. If the reverse method of connection is made, the trolley wire will lose the metal, the same being deposited on the trolley wheel, and in time the strength and conductivity of the wire must be seriously impaired, eventually resulting in breakages.

It is also important that existing systems of operating electric railways should be promptly taken in hand and the proper remedies intelligently applied. The three-wire system has been mentioned by some engineers as a possible solution.

I will here diverge for a minute to state that a trial was made four years ago under favourable conditions—not to avoid electrolysis, but to save copper. We developed physical difficulties of operation which warned us to avoid the three-wire system in future electric railway work.

I believe I am safe in stating that 90 per cent. of the electric railways have their systems so constructed as to largely restrict the conductivity of the rail circuit.

A one sided system is fundamentally wrong. The quantity of current to be controlled is so enormous that ordinary makeshift methods will not answer.

Having carefully analysed the whole matter, I feel justified in recommending that we must adopt the complete metallic circuit as the standard for the best electric railway practice. This can best be obtained by the following method:

1. By so bonding the track as to render the rail joints of as low resistance and nearly equal conductivity to the rails, and to execute this work so as to maintain this improved condition; and

2. The track system must be supplied with insulated feeders leading direct from the 'bus bars in the station to predetermined points of the track system, and thus offer a perfect low-resistance path for this side of the electric circuit, the same as obtained with the trolley line and the overhead system. All of these features and improved methods have been put in practice by the writer.

The only proper system is one that affords a well-insulated and complete metallic circuit of low resistance, that will give an ample path for the complete unrestricted circulation of the entire current from pole to pole of the dynamo, thus offering no inducement for the current to follow such conductors as gas or water pipes, but, as it were, actually robbing the earth of any desire to carry the current. I am not recommending extravagant methods, but only such as are deemed essential for economy, and of a practical nature for reducing expenses and augmenting dividends. The item of cost cannot properly be urged as an objection, because where the whole construction requires a large investment, every detail of the work should be so executed as to be permanent and enduring. If the details are carefully analysed it will be found that the cost of frequent reconstruction, maintenance, and renewals of rail bonds and bare wire amount to an excessive rate of interest on original investment, and would soon pay the small additional cost to build a complete metallic circuit. The superior service obtained from a complete metallic system of low resistance with the proper application of insulated track feeders will, within a brief period, more than refund a reasonable interest on the investment through the saving of fuel alone, not counting other economies in renewals and maintenance. The track-feeder system will be far less costly than the double-trolley system.

Whether track feeders should be laid underground or erected overhead is a question largely controlled by local conditions and capital available. I express a preference for underground work as being more permanent and subject to the least cost for repairs. The original construction is certainly more costly for underground. The actual cost of copper is the same in either. The necessity of constant repairs under existing methods, and the damage to water and gas pipes by electrolytic action, simply proves that it is but a question of time as to how long before electric railway companies will be forced to adopt the complete metallic circuit. Where experience and practical knowledge is applied, the cost will not be excessive. It is not difficult to arrive at an exact method of doing the work and an accurate estimate of its cost.

The writer has observed on some roads that large quantities of copper for return circuits have been placed at great expense, apparently without a proper conception of how to obtain the best results. Frequently a far less amount of copper, judiciously applied for improved distribution by the feeder system, would give superior equalisation of pressure at reduced cost.

Digitized by Google

If for the movement of cars singly or in quantities at a high rate of speed the electric current is to be distributed uniformly over an electric railway system, the subject must be handled with as much scientific accuracy as is always used for a perfect system of incandescent lighting, in order to obtain equal distribution and free flow of current in both sides of the system.

The writer has fully and completely provided for all contingencies in the following manner:

1. By a careful study of the conditions under which a system will be operated; these important points being ascertained with reasonable accuracy, the requisite supply and distribution of current for the service is determined, and the system of conductors arranged to meet the requirements. For the proper supply of electric current, the important underlying principles of the feeder system must be thoroughly understood.

2. The conductivity and current-carrying capacity of the track system is calculated, and a system of insulated track feeders is provided, leading from the switchboard in station and connecting at predetermined points, and with a calculated fall of potential.

Each feeder must be determined for its maximum current requirements at a stated drop in potential. The actual work required of the feeder and number of track feeders necessary is determined upon such factors as:

The cars in service—their weight, speed, and headway; the position of power station and the geographical lay of the railway system; the weight of rails, and whether double or single track, and the amount of load concentrated on sections of track between feeder junctions.

The carrying capacity or conductivity of the sum total of all the feeders of the system will be found to give complete and ample circuit for the free flow of the entire current required, and to take care of extra heavy traffic and blockades at any point.

The parallel track main is only applied in sections of systems extending over very large territories and long distances.

The conductivity of the rails is calculated with as much care as the overhead system, and when the track needs reinforcing, the purpose is accomplished by laying a thoroughly insulated main line (not a bare line) and making frequent sub-feeder connections bonded to the track. If used at all, this main will be of large size.

Such a system, accurately worked out, will show by actual test with instruments on the cars a surprising equality of E.M.F. throughout a large territory.

A very careful test has been made with instruments on moving cars, throughout a system covering 40 miles of streets, with double tracks, equal to 80 miles single track. The readings showed: maximum volts, 512; minimum volts, 420; average of E.M.F. over entire system, 460 volts; the E.M.F. in station, at 'bus bars, being 520 volts. The feeders were calculated for 10 per cent. drop. The actual average drop from dynamo to motor does not exceed 12 per cent.

This will be found to result in reduced fuel consumption, better working of the motors, a most satisfactory reduction in repair accounts, and an improved general economy of the entire system.

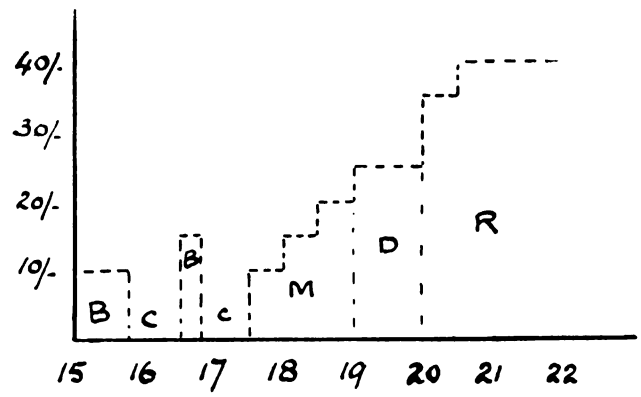
In the system of distribution secured by the above method, the use of ground plates, rods, or other insufficient methods is needless; the current travels only over the paths provided for it, and electrolysis of gas and water mains is entirely obviated.

A CAREER DIAGRAM.

We all remember the characteristic little incident in the life of one of our best engineers early in this century, when the "timmer" hat which he had turned in his "bit lathie," secured for the ingenious young Scotchman a position in which his capabilities found full scope for development, and made his after-life one of honoured labour.

There must have been something of the same originality of idea in a young electrical engineer who came to us a little while ago to see whether we knew of any opening through which he might carve his way to success in life along one particular direction: and one would feel inclined to say of him that the odds would be in his favour throughout.

On asking what he had done, the nature of his training and experience, etc., he brought out—not a written biography: "I left college at eighteen, spent two years with So-and-So, then went to Brown, Jones, and Co.'s works, etc."—but a diagram somewhat after the following style,



wherein was shown at once his career from the time of leaving school to date, as well as the rates of wages at which he had been paid. This "career curve" represents a young fellow's progress in an admirably clear and condensed form, and it would be to the advantage of all employers to insist on those who propose to enter their service presenting such a record in brief of their life and labour. Probably there might be thousands whose diagrams would not show up well, which is all the more reason for seeing them and comparing any in competition for a given post.

The young engineer in question explained his diagram as follows. He had as a boy spent much spare time in drawing, and at the age of 15 he found no difficulty in getting employment in an electrical works—B—as tracer, at 10s. a week. He stayed here for nine months, then spent the next nine months in theoretical and practical work in one of the electrical colleges to such good purpose that during the summer months he was taken on again by the same works at 15s. a week. Then the next session was given up to more practical work at the college testing-rooms, etc., with spare time devoted to picking up hints in a friend's machine-shop and foundry.

At the end of the college session he found no difficulty in getting employment on telephone and telegraph work for one of the railway companies—M—though to begin with his wages were only 10s. Regular advancement, however, doubled this in a year's time; and then an opening was offered with a firm of electric light contractors—D—at higher pay. After a year with them he again had a chance of improving his position with another firm—R—who were paying him 40s. weekly at the time of his call.

It need hardly be said that the ambitions of this young engineer bid fair to be very largely realised. It is just such men that are wanted to-day and always—men able to think and reason sensibly for themselves—and the more there are in the electrical industry the better for it.

NORTHERN SOCIETY OF ELECTRICAL ENGINEERS.

We give below a report of the discussion which took place on the papers read last week before this institution by Mr. John H. Rider, entitled "Notes on Designing a System of Underground Electric Light Mains," and by Mr. S. V. Clirehugh, A.M.I.C.E., on "Various Systems of Underground Mains and Methods of Laying Same." The papers were published in our last issue, and by the courtesy of Mr. J. Darney, the honorary secretary of the institution, we are now enabled to give the discussion on them:

Mr. Wordingham said: As regards the general questions of mains, from my point of view the most important thing is

Digitized by Google

durability rather than high insulation. Take the case of vulcanised rubber cable. In Whitehaven we had a resistance of 1,870 megohms—not per mile, but the whole system as laid. Suppose you put on 1,000 consumers, each of one megohm, then the insulation resistance would only be 1,000 ohms. It is no use putting thousands of megohms if the general resistance is only a few thousands. Under these circumstances I think the thing to be looked for is durability. There can be very little doubt that copper is durable; it sometimes corrodes, but I have not noticed it here except in one or two places where water has got into the boxes, and then only very slightly. As you know, we have in Manchester partly bare copper in culverts and partly rubber. The resistance of bare copper is low. As to actual figures, I should not care to give any without having considered the matter first, but the figures which have got about are rumours which are simply absurd—the resistance would only be a few ohms; instead of that it is certainly hundreds of ohms. As to rubber cables, I believe if the joints are properly vulcanised you can get perfect insulation. Of course, where rubber is joined on to bare copper, you must see that the braiding is properly pared back. With regard to the question of vulcanising joints the difficulty has been, I think, a little exaggerated; no doubt there is a large amount of difficulty in ascertaining the right duration of time for different mixtures and temperatures, but once the manufacturers gain this experience for you, and supply you with vulcanising material that is ascertained to be good, there is very little difficulty in vulcanising joints. I do not think the difficulty of vulcanising is great, and I think it is most unwise to omit it—it simply means an extra 20 minutes. The great convenience of bare copper is the ease of getting on consumers—you simply have to sweat on a pair of thimbles and clamp them on to the bare mains.

Mr. A. B. Mountain, of Huddersfield, observed: I think the two papers we have heard read are very interesting, and will require careful discussion. I cannot agree with some of the remarks referring to vulcanised indiarubber cables. There are, no doubt, certain difficulties in jointing these cables, but these difficulties are overcome by ordinary care. I think the system of drawing vulcanised cables through cast-iron pipes is in every way satisfactory for feeders or high-tension mains. The cables insulated with bitumen, paper, or fibre may be very good for low-tension mains, but are, I think, unsuitable for high-tension work unless laid with great care and at very considerable expense. You have just heard Mr. Wordingham speak of the insulation resistance of the Manchester mains. There, of course, you have the continuous-current system with probably all the consumers connected on to one network. In the case of a town supplied by an alternating current the network would be divided—I presume that is Mr. Rider's idea—and the risks arising from leaks very considerably reduced, because the number of consumers connected on any one section will be a small proportion of the total. It is a strong point with an alternating-current supply, the system being split up into small sections. In laying lead-covered cable underground, such as that proposed for Bolton, there are many points to be noticed. If the cables are laid in ground where there are traces of ashes, you get serious trouble. This has led in many gas undertakings to the adoption of galvanised wrought-iron pipes. Then the cables may be easily damaged by a blow from pick or spade. If the cable is stranded into three, twisted in a spiral form, in the centre of the three circles of insulating material there will be a space not properly filled in, along which I should anticipate moisture creeping, and also when connecting consumers to the three-wire mains some difficulty may be anticipated in ascertaining to which pair of cables the consumer shall be connected, and I should like to know how the cables are distinguished.

Mr. Bourne, of London, stated: There is one thing Mr. Rider mentioned in this, what I might call treble cable. Mr. Rider mentioned that the wires were twisted together, but separate action will depend upon the distance of the centres taking the circumference—*i.e*, it will depend upon the area enclosed. Mr. Clirehugh in many ways under-estimated the capacity of paper as an insulator. I am connected myself with a rubber cable manufacturing company, and I do not advocate the use of paper for putting on cables—it is not my trade. At one time I had the problem set before me to make a cable for an alternating high-pressure current that involved the use of paper, as we see in these cables. Mr. Clirehugh says the insulation on the samples shown is very thin—it seems to be about $\frac{1}{16}$in. The cables I made were successful, and the paper insulation had a thickness of about 17½ mils. There were seven thicknesses of the very finest paper. The cables worked at a pressure of 2,000 volts. You may get enormously high dielectric strength in paper—whether you can get them to combine the requisite strength with durability is a matter about which I have not had sufficient experience to say.

Mr. Corlett, in reply to the Chairman, said he thought it would be much more interesting for a cableman to speak who knew more of the system than he did.

Mr. Jas. Taylor remarked: I do not think I have any remarks—the only thing that struck me was that the difficulty of making rubber joints was over-estimated. This is really a simple matter, but it needs care. As regards paper and fibrous insulation, rubber has had 10 years' experience and paper has not, and in another seven or eight years we may know more about it.

Mr. Connolly said: Allow me to say a word as a cable-maker and as one who has had a fair amount of experience both in the manufacture and testing of cables. We have had two very interesting papers and some very interesting remarks from people who have to lay mains and make use of them, and I think they should look a little to the manufacturers for information on these particular points that they seem to be dubious about—viz., the durability of insulating materials and the trouble in jointing. As far as indiarubber is concerned, indiarubber has been used as an insulating material for nearly 30 years now, and in the earlier days of its use there were troubles and failures, but I know there are cables in use now covered with indiarubber that were made over 20 years ago still working successfully. It has often struck me that the experience in electric light work is more and more falling in line with the old telegraph work—that is to say, we are going back from the lower class of insulation to the higher class, and at the same time we are also going in a great deal more for the drawing-in system which is copied from the Post Office system for the telegraph wires. The only thing we do not follow the practice of the telegraph world in is in the use of guttapercha. The reason for this is obvious. The heat from the electric wires would melt the guttapercha and the cables would fall out of centre, and you would lose your insulation. I cannot conceive any permanent system of underground mains that does not consist of cables that are not insulated but are also insulated with waterproof material, because sooner or later there is bound to be trouble with the insulation unless you can rely upon the insulating material being impervious to water. With lead-covered cables, with cable depending upon the lead for protection, you have the constant danger of a break in the lead or trouble at the extremities—at the ends—and so long as you are dependent upon anything outside the insulating material for your protection you can never feel safe. I can hear on all hands our troubles with these underground copper mains, not so much in Manchester—things are new in Manchester—but in London, Paris, and elsewhere, even in places where there are supposed to be no troubles at all, and it has constantly been forced upon my mind that we cannot rely in a permanent way on anything which does not consist of conductors insulated throughout; and I do not know that indiarubber is the only material that can be used for the purpose, but it seems to be the only one that has been used so far that answers its purpose in any way. I should very much like myself to know of any cheaper material that has the same qualities—that is, as regards being waterproof, not liable to melt with a temperature of, say, 160deg. F., and at the same time as durable as we know indiarubber to be.

Mr. Whiteley observed: Mr. Taylor has spoken on the subject I had in my mind to speak about—the subject of making indiarubber joints. I think that is the only point on which my experience would be of any use. An intelligent workman could get into the way of making indiarubber joints after one or two trials, and very good ones, too. I do not think there is anything else I need speak about.

Mr. Clirehugh: I may say I withdraw my remarks about making indiarubber joints.

Mr. Cowan stated: With regard to Mr. Clirehugh's figures comparing the cost of laying armoured conductors direct in the ground with the same laid in cast-iron pipes, I estimate that for a $^{19}/_{14}$ concentric cable the cost of laying it in cast-iron pipes would be 10 per cent. more than burying the same cable, armoured, direct in the ground, including all costs. Mr. Clirehugh's figures for the cost of laying cast-iron pipes do not agree with mine. He gives the cost of laying 3in. pipes under flagging as 5s. per yard. I believe the gas companies would only allow 1s. 2d. per yard run, and my own experience gives a lower figure than this. I might say a word on the Brooks oil insulation system. I have tried it on a short line and found that it worked on the whole very satisfactory. The pressure was 2,000 volts. We had a dead short-circuit one night after a thaw, but it recovered its insulation the next day. The system did not seem so difficult to lay as Mr. Clirehugh makes out in his paper. I did not lay it, but merely watched the work being done.

Mr. Bourne observed that Mr. Clirehugh seemed to think 10 times a very severe test to subject a cable to. I think if he will take any reasonably good cable, say for 100 volts, it will stand from 10,000 to 25,000 volts—that is my experience. For instance, there was a cable I took out of the Crystal Palace—I do not know whose make it was—there was nothing extraordinary about it, but it took about 62,000 volts to break down that bit of rubber. It was only a short piece, and was being used for a 100-volt circuit.

Mr. Clirehugh: I said for that class of cable—that has nothing to do with rubber cable.

Mr. Andrew: I should like to mention as to the life of a cable. Although vulcanised rubber has only been used as an insulator for 10 or 12 years.

The **Chairman**: For 30 years.

Mr. Andrew: Vulcanised?

The **Chairman**: Yes, vulcanised rubber has been used for 30 years.

Mr. Andrew: Not to any extent.

A Member: Yes, thousands of miles.

Mr. Andrew: My point is this. Although it has not been used largely as an insulator of cables it has been used in other directions. For 40 or 50 years rubber has been vulcanised and specimens are still to be seen, so proving, as well as one can beforehand, that the well-made cables of to day will last at least that time in the future.

Mr. R. Taylor remarked: I should just like to state my experience as regarding vulcanised rubber. I have been engaged for the last 20 to 25 years in indiarubber cable-making at W. T. Henley's and other places. Iron tube cables were made and used for some years previous to that. Hooper's were the first makers, and made some very successful cables. Some were failures, and I do not know the cause; but since then some which were sup-

Digitized by Google

posed to be failures have been put under test, and found to be very good at the present time. A little has been said as to jointing. I do not think they should be treated lightly. I have made vulcanised joints 20 to 25 years ago, and the cables are working now in the German Ocean. My experience is that in vulcanised joints, with care, there is no fear of the joint going bad; the greatest care should be exercised, and the workman should be thoroughly trained. I do not think you should send out a jointer as competent after just showing him how the joint should be made. I think you should insist on the engineers sending their jointers to the manufacturer to be instructed, and not send him a few words on paper as instructions, as if you do it is quite certain that eventually some of the joints will break down; and I think engineers should insist on having their jointers thoroughly instructed in the matter of making a joint, and there will be no fear of their joints going wrong.

Mr. Wordingham said: I entirely agree with the last speaker. I should never think of sending out a jointer who was not thoroughly trained. In this city we have had men from the manufacturer of the cable to teach our men; perhaps a couple of months was devoted to teaching our staff. We have had them properly trained, and they have helped to vulcanise before being trusted to make joints themselves. The joints require very great care.

TRADE NOTES AND NOVELTIES.

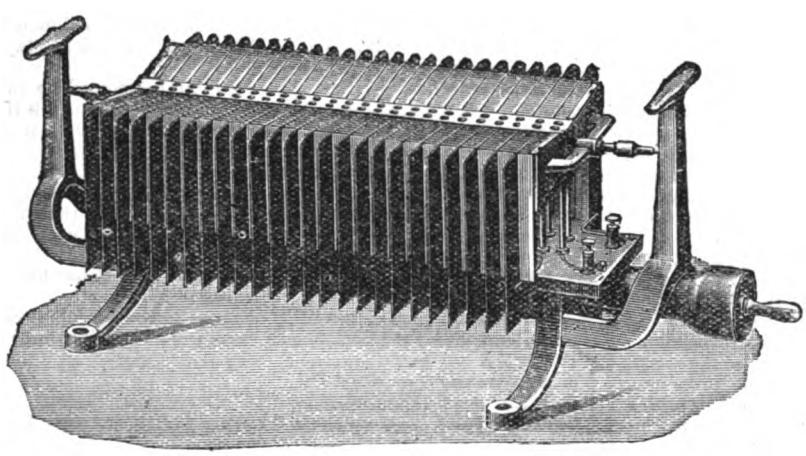
THE GULCHER THERMOPILE.

In many cases the use of powerful batteries, or even small dynamos for toy electrical purposes, may be considered to resemble very strongly the breaking of a butterfly upon a heavy wheel, and yet the waste of energy in generating apparatus of small output is extremely heavy whatever their type. Thermopiles of more or less inefficiency have been devised from time to time with the object of providing a constant source of supply without any trouble, and that devised by Gülcher is not by any means new to our readers, having been introduced to public notice on the Continent some time ago.

It is, however, only of late that this type of apparatus generating electricity by direct application of heat has been placed on the English market by the agents, Messrs. O. Berend and Co., of Fore-street, E.C., and we illustrate here with the most recent form of the appliance.

It consists—in the largest size—of about 32 thermo-electric couples, arranged in two rows with two intervening rows of small gas jets, represented in the illustration by the small holes down the middle of the top surface. In each of these holes is fitted a small cylindrical kaolin or porcelain burner; these get hot in about 10 minutes after lighting the gas, and then are found to give a small current at constant E.M.F. Of course, a flexible tube connection is used for the gas supply, which may be drawn from any source provided it pass through a regulator to maintain the pressure at the proper amount for which the burners are designed.

The makers claim that with 66 elements—having an internal resistance of ·65 ohm—a current of three amperes at four volts



is obtained when the external resistance is equal to the internal, at a consumption of gas not exceeding ·064 cubic foot per hour. This gives an extraordinarily low cost of electric enery, for assuming an output of six watts in the external circuit—*i.e.*, useful work done—the consumption of gas is only about 10½ cubic fect per Board of Trade unit. There are doubtless many purposes for which these appliances might prove serviceable, even at more normal prices for the energy obtained (to pay much less than 2d. or 3d. per unit savours almost of the "sovereign for a shilling" arrangement): for lectures, for working small induction apparatus, in laboratories, and other directions where quite small powers only are needed, there may be a considerable demand for these thermo-electric generators, if for no other reason than because they entirely obviate the trouble of refilling and cleaning batteries, etc.

THE BOARD OF TRADE AND ELECTRIC TRAMWAYS AND RAILWAYS.

THE OFFICIAL REGULATIONS FOR TRAMWAYS.

It will be remembered that in various Acts of Parliament and provisional orders granted last session authorising the use of electric traction on tramways, the duty was imposed upon the Board of Trade of prescribing regulations to be observed by tramway companies for the prevention of injury to gas and water pipes, and for minimising interference with other electric circuits. The Board of Trade having heard the various parties interested, has decided to prescribe regulations in the form given below:

REGULATIONS made by the Board of Trade under the provisions of the —— Tramways Act, for regulating the employment of insulated returns, or of uninsulated metallic returns of low resistance; for preventing fusion or injurious electrolytic action of or on gas or water pipes or other metallic pipes, structures, or substances; and for minimising as far as is reasonably practicable injurious interference with the electric wires, lines, and apparatus of parties other than the company, and the currents therein, whether such lines do or do not use the earth as a return,

Definitions.

In the following regulations, the expression "energy" means electrical energy; the expression "generator" means the dynamo or dynamos or other electrical apparatus used for the generation of energy; the expression "motor" means any electric motor carried on a car and used for the conversion of energy; the expression "pipe" means any gas or water pipe or other metallic pipe, structure, or substance; the expression "wire" means any wire or apparatus used for telegraphic, telephonic, electrical signalling, or other similar purposes; the expression "current" means an electric current exceeding one-thousandth part of one ampere; the expression "the company" has the same meaning as in the —— Tramways Act.

Regulations.

1. Any dynamo used as a generator shall be of such pattern and construction as to be capable of producing a continuous current without appreciable pulsation.*

2. One of the two conductors used for transmitting energy from the generator to the motors shall be in every case insulated from earth, and is hereinafter referred to as the "line"; the other may be insulated throughout, or may be uninsulated in such parts and to such extent as is provided in the following regulations, and is hereinafter referred to as the "return."

3. Where any rails on which cars run or any conductors laid between or within 3ft. of such rails form any part of a return, such part may be uninsulated. All other returns or parts of a return shall be insulated, unless of such sectional area as will reduce the difference of potential between the ends of the uninsulated portion of the return below the limit laid down in Regulation 7.

4. When any uninsulated conductor laid between or within 3ft. of the rails forms any part of a return, it shall be electrically connected to the rails at distances apart not exceeding 100ft. by means of copper strips having a sectional area of at least one-sixteenth of a square inch, or by other means of equal conductivity.

5. When any part of a return is uninsulated, it shall be connected with the negative terminal of the generator, and in such case the negative terminal of the generator shall also be directly connected, through the current indicator hereinafter mentioned, to two separate earth connections which shall be placed not less than 20 yards apart. Provided that in place of such two earth connections the company may make one connection to a main for water supply of not less than 3in. internal diameter, with the consent of the owner thereof and of the person supplying the water, and provided that where from the nature of the soil or for other reasons the company can show to the satisfaction of an inspecting officer of the Board of Trade that the earth connections herein specified cannot be constructed and maintained without undue expense, the provisions of this regulation shall not apply. The earth connections referred to in this regulation shall be constructed, laid, and maintained so as to secure electrical contact with the general mass of earth, and so that an E.M.F. not exceeding four volts shall suffice to produce a current of at least two amperes from one earth connection to the other through

* The Board of Trade will be prepared to consider the issue of regulations for the use of alternating currents for electrical traction on application.

Digitized by Google

the earth, and a test shall be made at least once in every month to ascertain whether this requirement is complied with. No portion of either earth connection shall be placed within 6ft. of any pipe except a main for water supply of not less than 3in. internal diameter which is metallically connected to the earth connections with the consents hereinbefore specified.

6. When the return is partly or entirely uninsulated the company shall in the construction and maintenance of the tramway (*a*) so separate the uninsulated return from the general mass of earth, and from any pipe in the vicinity; (*b*) so connect together the several lengths of the rails; (*c*) adopt such means for reducing the difference produced by the current between the potential of the uninsulated return at any one point and the potential of the uninsulated return at any other point; and (*d*) so maintain the efficiency of the earth connections specified in the preceding regulations as to fulfil the following conditions—viz: (i.) That the current passing from the earth connections through the indicator to the generator shall not at any time exceed either two amperes per mile of single tramway line or 5 per cent. of the total current output of the station. (ii.) That if at any time and at any place a test be made by connecting a galvanometer or other current indicator to the uninsulated return and to any pipe in the vicinity, it shall always be possible to reverse the direction of any current indicated by interposing a battery of three Leclanché cells connected in series if the direction of the current is from the return to the pipe, or by interposing one Leclanché cell if the direction of the current is from the pipe to the return. In order to provide a continuous indication that the condition (i.) is complied with, the company shall place in a conspicuous position a suitable, properly connected, and correctly marked current indicator, and shall keep it connected during the whole time that the line is charged. The owner of any such pipe may require the company to permit him at reasonable times and intervals to ascertain by test that the conditions specified in (ii.) are complied with as regards his pipe.

7. When the return is partly or entirely uninsulated a continuous record shall be kept by the company of the difference of potential during the working of the tramway between the points of the uninsulated return furthest from and nearest to the generating station. If at any time such difference of potential exceeds the limit of seven volts, the company shall take immediate steps to reduce it below that limit.

8. Every electrical connection with any pipe shall be so arranged as to admit of easy examination, and shall be tested by the company at least once in every three months.

9. Every line and every insulated return or part of a return except any feeder shall be constructed in sections not exceeding one-half of a mile in length, and means shall be provided for isolating each such section for purposes of testing.

10. The insulation of the line and of the return when insulated, and of all feeders and other conductors, shall be so maintained that the leakage current shall not exceed one-hundredth of an ampere per mile of tramway. The leakage current shall be ascertained daily before or after the hours of running when the line is fully charged. If at any time it should be found that the leakage current exceeds one-half of an ampere per mile of tramway the leak shall be localised and removed as soon as practicable, and the running of the cars shall be stopped unless the leak is localised and removed within 24 hours. Provided that where both line and return are placed within a conduit, this regulation shall not apply.

11. The insulation resistance of all continuously insulated cables used for lines, for insulated returns, for feeders, or for other purposes, and laid below the surface of the ground, shall not be permitted to fall below the equivalent of 10 megohms for a length of one mile. A test of the insulation resistance of all such cables shall be made at least once in each month.

12. Where in any case in any part of the tramway the line is erected overhead and the return is laid on or under the ground, and where any wires have been erected or laid before the construction of the tramway in the same or nearly the same direction as such part of the tramway, the company shall, if required so to do by the owners of such wires or any of them, permit such owners to insert and maintain in the company's line one or more induction coils or other apparatus approved by the company for the purpose of preventing disturbance by electric induction. In any case in which the company withhold their approval of any such apparatus the owners may appeal to the Board of Trade, who may, if they think fit, dispense with such approval.

13. Any insulated return shall be placed parallel to and at a distance not exceeding 3ft. from the line when the line and return are both erected overhead, or 18in. when they are both laid underground.

14. In the disposition, connections, and working of feeders the company shall take all reasonable precautions to avoid injurious interference with any existing wires.

15. The company shall so construct and maintain their system as to secure good contact between the motors and the line and return respectively.

16. The company shall adopt the best means available to prevent the occurrence of undue sparking at the rubbing or rolling contacts in any place and in the construction and use of their generator and motors.

17. In working the cars the current shall be varied as required by means of a rheostat containing at least 20 sections, or by some other equally efficient method of gradually varying resistance.

18. Where the line or return or both are laid in a conduit the following conditions shall be complied with in the construction and maintenance of such conduit: (*a*) The conduit shall be so constructed as to admit of easy examination of and access to the conductors contained therein and their insulators and supports. (*b*) It shall be so constructed as to be readily cleared of accumulation of dust or other *débris*, and no such accumulation shall be permitted to remain. (*c*) It shall be laid to such falls and so connected to sumps or other means of drainage, as to automatically clear itself of water without danger of the water reaching the level of the conductors. (*d*) If the conduit is formed of metal, all separate lengths shall be so jointed as to secure efficient metallic continuity for the passage of electric currents. Where the rails are used to form any part of the return they shall be electrically connected to the conduit by means of copper strips having a sectional area of at least one-sixteenth of a square inch, or other means of equal conductivity, at distances apart not exceeding 100ft. Where the return is wholly insulated and contained within the conduit, the latter shall be connected to earth at the generating station through a high resistance galvanometer suitable for the indication of any contact or partial contact of either the line or the return with the conduit. (*e*) If the conduit is formed of any non-metallic material not being of high insulating quality and impervious to moisture throughout, and is placed within 6ft. of any pipe, a non-conducting screen shall be interposed between the conduit and the pipe, of such material and dimensions as shall provide that no current can pass between them without traversing at least 6ft. of earth, or the circuit itself shall in such case be lined with bitumen or other non-conducting damp-resisting material in all cases where it is placed within 6ft. of any pipe. (*f*) The leakage current shall be ascertained daily, before or after the hours of running when the line is fully charged, and if at any time it shall be found to exceed half an ampere per mile of tramway the leak shall be localised and removed as soon as practicable, and the running of the cars shall be stopped unless the leak is localised and removed within 24 hours.

19. The company shall, so far as may be applicable to their system of work, keep records as specified below. These records shall, if and when required, be forwarded for the information of the Board of Trade.

Daily Records.

Number of cars running.
Maximum working current.
Maximum working pressure.
Maximum current from the earth connections (*vide* Regulation 6 (i)).
Leakage current (*vide* Regulations 10 and 18 (*f*)).
Fall of potential in return (*vide* Regulation 7).

Monthly Records.

Condition of earth connections (*vide* Regulation 5).
Insulation resistance of insulated cables (*vide* Regulation 11).

Quarterly Records.

Conductance of joints to pipes (*vide* Regulation 8).

Occasional Records.

Any tests made under provisions of Regulation 6 (ii.).
Localisation and removal of leakage, stating time occupied.
Particulars of any abnormal occurrence affecting the electric working of the tramway.

PROPOSED REGULATIONS FOR ELECTRIC RAILWAYS.

The foregoing regulations only concern tramways worked by electricity, but as during last session certain Acts of Parliament were granted authorising the use of electric traction on railways to be constructed underground in metal-lined tunnels, the duty has again devolved upon the Board of Trade to prescribe regulations for the prevention of injury to gas and water pipes, and for minimising interference with other electric circuits. In this connection the following draft regulations have been prepared and submitted for the consideration of the Board of Trade:

DRAFT REGULATIONS made by the Board of Trade under the provisions of the —— Railway Act, for regulating the employment of insulated returns, or of uninsulated metallic returns of low resistance; for preventing fusion or injurious electrolytic action of or on gas or water pipes or other metallic pipes, structures, or substances; and for minimising as far as is reasonably practicable injurious interference with the electric wires, lines, and apparatus of parties other than the company, and the currents therein, whether such lines do or do not use the earth as a return.

Definitions.

In the following regulations the expression "energy" means electrical energy. The expression "generator" means the dynamo or dynamos or other electrical apparatus used for the generation of energy. The expression "motor" means any electric motor carried on a train and used for the conversion of energy. The expression "pipe" means any gas or water pipe or other metallic pipe, structure, or substance. The expression "the company" has the same meaning as in the —— Railway Act.

Regulations.

1. Any dynamo used as a generator shall be of such pattern and construction as to be capable of producing a continuous current without appreciable pulsation.*

* The Board of Trade will be prepared to consider the issue of regulations for the use of alternating currents for electrical traction on application. Note.—These regulations only apply to railways constructed underground in metal-lined tunnels.

Digitized by Google

2. One of the two conductors used for transmitting energy from the generator to the motors shall be in every case insulated from earth by means of insulators of a strong and durable material so shaped as to offer great resistance to surface leakage, and is hereinafter referred to as the "line"; the other may be similarly insulated throughout, or may be uninsulated in such parts and to such extent as is provided in the following regulations and is hereinafter referred to as the "return."

3. Where any rails on which trains run or any conductors laid within the metal-lined tunnels in which the railway is constructed form any part of a return, such part may be uninsulated. All other returns or parts of a return shall be insulated.

4 When any uninsulated conductor forms any part of a return, it shall be electrically connected to the rails at distances apart not exceeding 100ft. by means of copper strips having a sectional area of at least one-sixteenth of a square inch, or by other means of equal conductivity.

5. When any part of a return is uninsulated it shall be connected with the negative terminal of the generator, and in such case the negative terminal of the generator shall also be directly connected to the iron or other metal plates forming the lining of the tunnels. In each case the connection shall be made through a suitable current indicator.

6. The iron or other metal plates forming the lining of the tunnels shall be so made and connected together as to form a continuous metal tube.

7. Where any pipe is brought into the tunnel from outside, means shall be provided to secure that no portion of the pipe outside the metal tube shall be in metallic connection with the tube or with any conductor of electricity within the tube.

8. When the rails form any part of the return they shall either be electrically connected, at intervals not exceeding 100ft., to the metal tube by metallic conductors which will not be appreciably heated by a current of 100 amperes, or they shall not be in any metallic connection with the metal tube except by means of the connections to the negative terminal of the generator. In the latter case the rails shall be supported by cross sleepers of wood specially prepared to resist the penetration of moisture and the growth of any mould or fungus, and they shall be of such sectional area and so connected at joints and from one line of rails to another, and where necessary to supplementary conductors or feeders, that the difference of potential between the rails and the metal tube shall not in any part and under any working conditions exceed 10 volts. A test of this shall be made at least once in each month.

9. When the return is partly or entirely uninsulated a continuous record shall be kept by the company of the difference of potential during the working of the railway between the points of the uninsulated return furthest from and nearest to the generating station. If at any time such difference of potential exceeds the limit of seven volts, the company shall take immediate steps to reduce it below that limit.

10. Every line and every insulated return shall be constructed in sections, and means shall be provided at or near each station for breaking the connection between sections for the rapid localisation of faults.

11. The insulation resistance of any conductor laid outside the metal tube shall not be permitted to fall below the equivalent of 10 megohms for a length of one mile. A test of this shall be made at least once in each month.

12. The leakage current shall be tested daily before and after the hours of running with the working pressure and duly recorded. Should the amount of this at any time appear to indicate a fault of insulation, steps shall at once be taken to localise and remove it.

13. The company shall, so far as may be applicable to their system of working, keep records as specified below. These records shall, if and when required, be forwarded for the information of the Board of Trade.

Daily Records.

Number of trains running.
Maximum working current.
Maximum working pressure.
Maximum current from the rails to generator.
Maximum current from the metal tube to generator.
Leakage current (*vide* Regulation 12).
Fall of potential in return (*vide* Regulation 9).

Monthly Records.

Maximum difference of potential between rails and metal tube (*vide* Regulation 8).
Insulation resistance of conductors laid outside metal tube (*vide* Regulation 11).

Occasional Records.

Localisation and removal of leakage, stating time occupied.
Particulars of any abnormal occurrence affecting the electric working of the railway.

LEGAL INTELLIGENCE.

THE WINNIPEG STREET RAILWAY COMPANY v. THE WINNIPEG ELECTRIC STREET RAILWAY COMPANY AND THE CITY OF WINNIPEG.

This was an appeal heard a few days ago before the Judicial Committee of the Privy Council from a judgment of the Court of Queen's Bench of the Province of Manitoba, of May 13, 1893, affirming a decision of Mr. Justice Bain. The Lord Chancellor, Lord Watson, and Sir Richard Couch were present.

The Solicitor-General, the Hon. Edward Blake, Q.C. (of the Canadian Bar), and Mr. F. C. Gore were for the appellants; Mr. Finlay, Q.C., Mr. J. H. Munson, and Mr. F. W. Hollams for the Winnipeg Electric Street Railway Company; and Mr. Ewart, Q.C. (of the Canadian Bar), and Mr. Bray for the city of Winnipeg.

The principal question raised in the appeal was whether the city of Winnipeg could validly grant to the Winnipeg Electric Street Railway Company a right to lay down street railways and to run cars within the city in streets already worked by street railways of the appellant company and in streets not yet worked by the appellants, but in which the latter were willing to work. The appellants contend that the city of Winnipeg was precluded from granting competing rights to the respondent company in either case, both by the terms of their statutory powers and also by an agreement made with them (the appellants). The respondents assert that no exclusive right was conferred on the appellants in the matter, and that any contract purporting to have that effect was *ultra vires* and not binding

At the conclusion of the arguments for the appellants,

The Lord Chancellor said their Lordships would not require to hear counsel on the other side. They would deliver judgment on a future occasion.

COMPANIES' MEETINGS.

DIRECT SPANISH TELEGRAPH COMPANY.

The ordinary general meeting of the Direct Spanish Telegraph Company, Limited, was held on Tuesday at the offices, Winchester House, Old Broad-street, Sir John Pender, M.P., presiding.

In moving the adoption of the report, the **Chairman** stated that, after providing for debenture interest, there was a balance to the credit of profit and loss of £4,996. The Falmouth-Bilbao cable became interrupted last August, but it was promptly repaired by the Eastern Company's ship, the "Electra." Satisfactory results had attended the opening last November of the branch office in the Foreign Auction Hall, Covent Garden Market, where a great portion of the fruit trade with Spain was carried on. He would like to have an interview some day with the preference shareholders, as he believed he would be able to show them that it might be better for them to attach their interests more closely to those of the other shareholders and to the general progress of the Company. He believed that with a little judicious handling the position might be made a little fairer all round.

Mr. Edmund Etlinger seconded the motion, which was adopted.

OXFORD ELECTRIC LIGHT COMPANY, LIMITED.

The third ordinary general meeting of the shareholders has been held at the offices, Broad-street, Oxford, under the presidency of the chairman, Sir Henry C. Mance, C.I.E.

The report was as follows: "The directors beg to submit to the shareholders the accounts made up to December 31, 1893, in the form prescribed by the Board of Trade. The revenue account shows a profit of £1,105. 7s, and after providing for the full interest on the debentures issued up to December 31, 1893, there remains a balance of £68. 8s. 5d., which the directors recommend should be carried forward to next account. The balance of £612. 9s. 1d. appearing to the debit of the profit and loss account, 1892, has not been brought forward into the account for the past year, as the contractors under a general settlement with the Company have refunded an amount which the directors have applied to cancelling the preliminary expenses and the balance to debit of the revenue account referred to. During the last year the running of the plant has continued to give entire satisfaction. About 3 000 8-c.p. lamps have been added to the system, and the directors have every reason to hope that the progress during the present year will not be less satisfactory. Since the last report extensions have been made to King Edward's-street, Mansfield-road, St. Giles's, St. Aldate's, and Magdalen College. The total number of lamps installed on December 31 was equivalent to 7,012 8-c.p. lamps. Ten colleges are now connected to the system, and others are expected to instal the light during the present year. 103,895 Board of Trade units were delivered to customers during 1893. The expenditure of coal per unit delivered and metered has been ·718 of a penny, which compares favourably with the results obtained by the majority of central supply stations The directors who retire by rotation are Mr. R. Buckell and Mr. J. L Courtenay, who offer themselves for re-election. Mr. W. S. Carver, the auditor, retires, but offers himself for re-election."

The **Chairman**, in moving the adoption of the report and accounts, said that in consequence of a general settlement with the contractors they had been able to open the accounts of 1893 without bringing forward the adverse balance which appeared in the balance-sheet for the preceding year. The accounts for the year were in a somewhat different form to those previously submitted, and they were now presented exactly in the form prescribed by the Board of Trade. They had still a small amount of debenture capital unissued, but it would be required probably for various extensions which they contemplated carrying out during the year. Considering the short time the Company had been in operation he thought the revenue account shou'd be regarded as extremely satisfactory. They had written nothin;

Digitized by Google

off for depreciation, but, on the other hand, there was an item of £396 for the maintenance of machinery and plant, and his impression was that after the expense on the batteries the plant was in better order now than when it was laid down. After providing for debenture interest there remained a balance to the credit of the net revenue account of £68. 8s. 5d., which had been carried forward to the present year. The number of 8-c.p. lamps connected to the system had increased from 4,040 to 7,012, and the number of consumers had increased from 65 to 100. They proposed extending their mains almost immediately to Beaumont-street, Pembroke College, across Magdalen Bridge to the new Magdalen Schools, and the square on the other side of the bridge. The question of extending the mains so as to embrace the residential district in the north of Oxford was receiving serious consideration. The efficiency of the system worked out at about 63 per cent., which compared favourably with other systems. They had not introduced a sliding scale into the town, but they had as a substitute given 5 per cent. discount for cash payments. They had 7,000 lights connected with the mains, whereas their present capacity was at least 15,000, and it was a very hopeful feature for the future that their station could be, at a comparatively small expenditure, so expanded and altered as to bring their capacity up to 30,000 or 35,000 lamps if necessary.

Mr. Bigge seconded the motion, which was carried unanimously.

On the motion of the **Chairman**, seconded by **Mr. Garcke**, Messrs. Buckell and Courtenay were re-elected directors, and Mr. Carver was reappointed auditor. A vote of thanks to the chairman terminated the proceedings.

COMPANIES' REPORTS.

HOUSE-TO-HOUSE ELECTRIC LIGHT SUPPLY COMPANY, LIMITED.

Directors: Henry Ramié Beeton (chairman), William Reginald Davies, Robert Arthur Germaine, William Francis Leese, William Page. Secretary: W. Coupland Weir.

Report of the directors and abstract of accounts for the year ended December 31, 1893.

In submitting to the shareholders the balance-sheet and accounts for the year ended December 31, 1893, the directors beg to report that the revenue account shows a credit balance of £4,231. 4s. 2d., which, with the sum of £525 guaranteed by the Leeds and London Electrical Engineering Company, Limited, referred to in paragraph 7, and the balance, £40. 14s. 3d., brought forward from the previous year, makes a total of £4,796 18s. 5d. After deducting £1,800 for interest paid on £30,000 debentures, it is proposed to deal with the balance as follows:

	£ s. d.
In reduction of preliminary expenses	500 0 0
In reduction of suspense renewals account	100 0 0
Depreciation fund	700 0 0
Dividend of 7 per cent. on £25,000 cumulative preference shares	1,653 10 2
Balance carried forward to next account	43 8 3
	£2,996 18 5

That the Company's business has continued to increase from January 1, 1890, is shown by the table given below.

It is most satisfactory to observe that, whereas the revenue derived from the sale of current shows an increase of £1,421 over last year, the working expenses show a decrease of £19. Since the issue of the last report another engine and alternator have been laid down, bringing the capacity of the station, exclusive of reserve, to 45,000 8-c.p. lamps. The balance of the issue decided on, of £25,000 7 per cent. cumulative preference shares, has been subscribed during the past year. The guaranteed sum of £525 has been credited in account by the Leeds and London Electrical Engineering Company, Limited, for the year 1893, in connection with the business of central-station construction which that company took over. The directors are pleased to report that the application to the Board of Trade to revoke that portion of the Company's provisional order which referred to the northern division of the area of supply has been successful and the Company are now released from their obligation to lay mains in that district. Mr. Robert Hammond has retired from the Board, and has been appointed consulting engineer to the Company. The directors received with regret last year the resignation of their manager, Mr. Albert Gay, on his appointment as resident engineer to the Vestry of St. Mary's, Islington. They have appointed Mr. Henry W. Bowden as chief engineer, and have every reason to be satisfied with their selection. Mr. W. F. Leese and Mr. W. R. Davies retire from the Board by rotation, and being eligible offer themselves for re-election. Messrs. Theobald Bros., Miall, and Co., the auditors of the Company, retire, and submit themselves for re-election.

BUSINESS NOTES.

Western and Brazilian Telegraph Company.—The receipts for the week ended March 16 were £3,550.

International Cable Company.—A dividend of 20s. in the £ is announced by the liquidator to the creditors.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 18th inst. amounted to £707.

Leamington.—The tenders received by the Town Council for the telephone have been referred to the General Purposes Committee with power to act.

West India and Panama Telegraph Company.—The receipts for the two weeks ended March 15 were £189 less than for the corresponding period of 1893.

Blackpool.—The new Park Hotel, which Messrs. Lord and Rushton intend to convert out of the old Claremont Hotel, Blackpool, is to be lighted by electricity.

Chelsea Supply Company.—The letters of allotment for the Chelsea Electricity Supply Company, Limited, 6 per cent. preference shares have been posted.

Electricity-Users' Association, Limited.—This Company has been registered with a capital of £2,000 in £1 shares, to insure against all kinds of accidents to electrical apparatus.

Tramcars.—The South London Tramways Company are making experiments in the electric lighting of tramcars. It is said to be probable that the company will introduce this system in all the cars.

Sutton.—The Sutton (Surrey) Local Board invite, by April 4, tenders for the purchase of the powers granted to them by the Board of Trade under the Sutton (Surrey) Electric Lighting Order. Further particulars can be obtained of the surveyor.

Warminster.—A discussion took place at the last meeting of the Local Board with regard to the electric light. Mr. Morgan said he intended consulting an expert to see if something could be done to prevent the dark shadows at present cast by the light.

Fleetwood.—The Improvement Commissioners have referred the question of obtaining complete specification for the proposed electric lighting station in the town's yard to Messrs. Monk and Drummond. The clerk reported last week that the Brush Company were preparing the specification for the works at the town's yard.

Tenders for Boilers.—As stated in our last issue, tenders are required by the 31st inst. for the supply and delivery at their Neepsend works of three Lancashire steel boilers, each 30ft. long by 7ft. 6in diameter, for the Sheffield United Gaslight Company, Neepsend Station.

Tipton.—A plot of land, situated at the factory in close proximity to the railway and canal, has been acquired by Messrs. Buller, Jobson, and Co., electrical engineers, Phœnix Works, Dudley, who, it is stated, propose erecting thereon an extensive galvanising and engineering plant.

City and South London Railway.—The receipts of the Company for the week ending March 18 were £926, against £880 for the same period last year, or an increase of £46. The total receipts for the first half-year of 1894 show a decrease of £12 compared with those for the corresponding period of 1893.

Hove Electric Lighting Company, Limited.—Two fresh issues are announced by this Company, the first consisting of the balance of 3,954 ordinary shares of £5 each, and the second comprising £12,500 in 5 per cent. debentures of £50 and £100 each. In both cases the price of issue is par. The debentures are secured as a first charge upon the whole of the property of the Company.

Arc Lamp Carbons.—Messrs. Ohnemüller and Ulrich, of the Oberfränkische Porzellanfabrik, Küps, Bavaria, inform us that they have appointed Messrs. E. Wallace and Co., of 30-31, Newgate-street, London, E.C., agents for their arc lamp carbons. These carbons are guaranteed by the makers to burn perfectly clean and steady, and they are suitable for both direct and alternating currents.

Oriental Telephone and Electric Company, Limited.—This Company has been registered with a capital of £200,000 in £1 shares to acquire the undertaking of the Oriental Telephone and Electric Company, Limited (now in liquidation). The first signatories to the memorandum of association are: W. Addison, T. Lloyd, G. B. Frost, A. B. Chalmers, B. St. J. Ackers, H. A. Hentsch, and H. Grewing.

Scarborough.—The Electric Light Sub-Committee of the Town Council have had before them a report by Mr. Bernard Drake on the work carried out by the Scarborough Electric Supply Company, Limited, in which some slight alterations were suggested. The town clerk has been instructed to send a copy of the report to the company, and request them to carry out forthwith the recommendations contained therein.

Support for Electric Candles.—Messrs. Faraday and Son have brought out a device the object of which is to afford, by means of triplex springs taking a double bearing, a steady support for imitation candles used in adapting the electric light to sconces and candelabra. The unsightly effect of candles standing at various angles is thus overcome. The candles may be easily removed for cleaning without interfering with the electrical connections.

Dover.—The work of wiring the Town Hall is nearly finished, and the exhibition which the Mayor announced in the Town Council a short time ago will take place during April. The Town Council have received a further letter on the subject of electric light regulations from the Board of Trade, and a copy of the amended regulations as applied to the Dover Company. The alterations referred to the more efficient insulation of the lamp columns.

New Clock at Bankside.—The City of London Electric Lighting Company have just had a clock erected at their new works, Bankside, Southwark. The order to make and fix it was entrusted to Mr. J. W. Benson, of Ludgate-hill and Old Bond-street, who has recently completed a clock which shows time on a 4ft. 6in. illuminated dial on the outside and a 4ft. 6in. copper dial on the inside. It strikes the hours on a 3cwt. bell. All the wheels are of the best gunmetal, and it is fitted with a compensated pendulum.

Waterloo and City Railway.—Applications have this week been invited for 54,000 shares of £10 each of the Waterloo and City Railway Company. The Company was incorporated in 1893, with a share capital of £540,000, and borrowing powers of £180,000, to construct a tunnel line, about one mile and a half in length, commencing under the platforms of the Waterloo Station, crossing the Thames near Blackfriars Bridge, and terminated at a point nearly opposite the Mansion House, without any intermediate station, the motive power to be electricity.

Stirling.—At a meeting of the Stirling Town Council a letter was read from the Board of Trade stating that they proposed proceeding with the application of the Caledonian Electric Supply Company for a provisional order, and presumed the Council's opposition to the application would now be withdrawn. The clerk was instructed to reply that the Council before withdrawing their opposition wished an opportunity of making terms with the company, and a special committee was appointed to watch over the matter in the interests of the ratepayers.

Lighting of Papermills.—An electric light installation has been introduced in the Watchett Papermills, Somersetshire. The proprietors, Messrs. Wansbrough and Worral, entrusted the work of installing the electric light to the Newton Electric Engineering Company, of Taunton. The fixing of the wires and plant has been under the superintendence of Messrs. H. Osborne and A. Miller. The current is generated by a Newton compound dynamo, which is driven by steam, but water power can be utilised when required, and the light is distributed all over the mills. There are installed 155 incandescent lamps.

Weston-super-Mare.—At the last meeting of the Town Commissioners a memorial from local tradesmen and ratepayers was

Digitized by Google

read, requesting the Commissioners to put into force the powers obtained for the installation of the electric light. The Chairman said that the time had come when the lighting question should be considered. Their loans would soon be consolidated, and the matter was ripe for consideration. He would suggest that the memorial be handed to an electric light committee, who could report thereon to the Board. After some discussion, an electric light committee was formed to consider the matter.

Refuse and Steam Generation.—The prospectus has been issued of the London Refuse Steam Generator and Electrical Power Corporation, Limited, which has been formed for the purpose of acquiring the rights for London and 20 miles round of working Livèt's patents for destroying town refuse, and for the generation of heat in furnaces (by the utilisation of dust and refuse) for electric lighting and other purposes. The capital of the company is £600,000 in shares of £1 each. The purchase price is £400,000, of which the vendors stipulate for £200,000 in shares, and for the balance in cash or shares, at the option of the directors.

Atlas Carbon Company.—The Atlas Carbon Manufacturing Company, Limited, of 19, Ewer-street, London, S.E., make a speciality of Leclanché batteries, of which they produce thousands weekly. The Company make the battery from beginning to end, and being carbon manufacturers they are able to work economically and ensure quality. The Company supply Leclanché cells, complete, in the porous pot form and in the agglomerate block form; porous pots (charged); agglomerate blocks, battery plates, plain or capped, and carbons of all kinds. Large stocks of the following goods are held at the Company's works: battery glasses, salammoniac, battery manganese, porous pots, zincs, crushed carbon, etc.

Yarmouth.—The Town Council have received 26 tenders for the laying down of the electric light installation, but only six of these were complete tenders. The lowest tender was Messrs. Crompton's, at £12,578. 4s., and the highest Mr. H. South's, at £19,624. The committee accepted the former, and the town clerk has been authorised to fix the corporate seal to the contract. The Surveyor stated at a meeting of the Council last week that the cost of the electric lighting works at the prices of the accepted tenders would be £16,200, whilst the loan sanctioned by the Local Government Board was only for £15,000. The Council resolved to apply to the Local Government Board for sanction to borrow an additional £1,500. The committee's report was adopted.

Electric Cooking and Heating Appliances.—Messrs. Crompton and Co., Limited, recently gave an exhibition of electrical heating and cooking appliances at the Sanitary Institute before the Duchess of Albany and a large company of ladies. Mr. H. J. Dowsing, who had charge of the exhibition, showed electric ovens, hot-plates, radiators, foot-warmers, etc., at work. Her Royal Highness took great interest in the apparatus, and was particularly struck with the perfect cleanliness of the cooking arrangements. She asked various questions with regard to the principles of construction and as to how the heat was obtained. The convenient system of regulating the heat of the ovens was particularly noticed, and the possibility of warming rooms without vitiating the atmosphere by means of electric radiators gave great satisfaction. At the close of the exhibition, her Royal Highness expressed herself as delighted with what she had seen, and personally thanked the demonstrator for the explanations he had given as to the working of the appliances.

New Installations.—Messrs. Gent and Co., of Faraday Works, Braunstone Gate, Leicester, have just completed the lighting of the printing and composing rooms and library of the *Folkestone Herald*. The plant consists of an 8-h.p (brake) Robey gas-engine fitted with balanced crank for steady running and noiseless exhaust chamber, the firm's "high-class" dynamo, and all fittings complete for an output of 80 lights of 16 c.p. Messrs. Gent and Co. have also just finished an installation for Messrs. Jermyn, Smith, and Co., drapers, of Peterborough, where not only are the company's drapery establishments lighted, but also the adjoining shops and a bank. The motive power is provided by a Robey gas-engine, the dynamo being one of the company's "high-class" dynamos. This is the first installation for shop-lighting in Peterborough. The same firm have secured the contract for lighting the Hotel Wampach, Folkestone. This plant will also be driven by a Robey gas-engine. The contract includes a set of accumulators, a dynamo, and all fittings for 150 16-c.p. Edison and Swan lamps, the principal rooms to be provided with elaborate electroliers.

A Cold Galvanising Process.—With the object of cheapening the process of coating iron with zinc and of avoiding the deterioration of the quality of the material which usually follows pickling and hot galvanising, Mr. Cowper-Coles, of 16, Adam-street, W., has invented a process for coating iron with spelter in a cold condition. Messrs. Laird Bros., of Birkenhead, were the first to adopt the cold galvanising process, and erected a plant for the purpose of cold-coating plates up to 18ft. long with zinc. The articles to be so treated are first pickled and then passed through a washing-tank, or oxidising-tank, after which they are removed to the plating-bath by means of an overhead trolley running on rails. To quicken the process, retain a smooth surface, and prevent any reduction in the tensile strength, an electric current is passed through the pickling-tank. Several shipbuilders are now erecting plants capable of dealing with plates 25ft. long, and of coating the frames of small craft, such as torpedo-boat destroyers, after riveting up. As the result of experiments made to ascertain the relative tensile strength, etc., of specimens cut from steel-plate strips, treated by the cold process and by the ordinary hot method, it was found that the elastic stress of the plates zinc-plated was 17·4 tons per square inch, as against 16 5 tons by the old method, the ultimate stress being 26·3 tons and 27·9 tons, and the extension in 10in., 24·9 and 22 6 per cent. respectively. Tests made to determine the adhesion of the zinc plating, as compared with hot galvanising, showed that, whilst in the latter case the coating began to scale at from 57.750lb. to 63,130lb. per square inch, the zinc plating did not scale, but remained intact throughout the experiments. It is claimed that the cold process is quite 40 per cent. cheaper than the hot, and there is no warping or distorting of articles of small section.

The National Telephone Company's Irish Policy.—"In our columns yesterday," the *Irish Times* of Tuesday's date remarks, "Mr. James H. North referred to a 'rather curious departure in the matter of its agreements,' with Irish users of the instrument, by the National Telephone Company. 'Lately the Company has adopted the 1st of January as its gale day, and all recent or new tenancies run from that date. In a circular issued a month or so back, subscribers were informed that on their signing agreements for five years the rents would be reduced to £10 per annum, the reduction to date from January last in all tenancies running from that date, but not to affect other tenancies till the expiration of the present year. Under this rule I and the other tenants whose years began on the 1st October must pay the higher rent for the current 12 months, while a subscriber who only joined on the 1st January last gets the benefit from that day. This, to my mind,' says Mr. North, 'is a palpable injustice.' It is an evidently reasonable protest if the amount involved is small to each individual, and Mr. North's clear and forcible statement was sure to attract notice. To-day, accordingly, Mr. D. O'C. Miley opens up a further departure of the Company which we think more curious still. 'The proposed (diminished) rental of £10 per annum is only to take effect if the subscriber signs an agreement binding himself to continue his subscription for a period of five years.' This agreement, it appears, contains a clause that if, from any cause whatever, the yearly rent is in arrear for a month, or if the subscriber becomes insolvent,' or in any way violates any of the 14 other long provisions of the agreement, the whole £50 shall thereupon immediately become payable as liquidated damages to the Company.' Our second correspondent refuses to sign any such agreement. He has been, along with others, since 1883 expecting a reduction of rate, and instead has this complicated penal arrangement offered to him. The five years' plan, as far as we see, cannot be approved. We should like to hear the grounds upon which it is judged necessary. Unless some very sufficient and satisfactory reasons can be adduced, which it is not possible to imagine, the movement of remonstrance commenced so well by Mr. North in his letter, and seconded as we now state, is sure to grow and extend among the Company's discontented tenants."

Electric Lighting of Derry.—The contractors' test of the electric lighting plant in Derry took place on Saturday evening, when the streets were lighted from seven till half-past ten o'clock. It is not intended to light the city permanently for a week or two yet. Among those who attended were Councillor T. S. Magee, chairman of the Lighting Committee; Aldermen Bell and Johnston; Councillors Turner, Thompson, Brewster, Taaffe, and Young; Prof. Leebody, D Sc.; Mr. H. W. Blake, consulting electrical engineer; Mr. W. J. Robinson, city surveyor; Mr. R. E. Buchanan, C.E.; Mr. William Colhoun; Mr. R. H. Algeo; Mr. Collings, Messrs. Siemens Bros.' engineer; Mr. Mittlehausen; Mr. Clamp, engineer for Messrs. Johnson and Phillips; and several members of the firm of Messrs. Alex. Brown and Sons. The floor of the machinery-hall might be described as one huge mass of solid concrete, the engine foundations, which extend some 9ft. into the earth, reaching halfway across the room, and only separated from the dynamo foundations by the condenser-pipe trench which connects the condensing engines with the water of the river. The same description is applicable to the boiler-house. The chimney is 125ft. in height above the floor-level, besides 20ft of foundation buried in the earth. The projection of the cap at the top is well proportioned and symmetrical. The structure has been pronounced by authorities to be one of the best in Ulster. It is designed to meet the requirement of any extension of the electric lighting scheme which might be carried out in the future. Mr. R. E. Buchanan was the engineer for this part of the work, and Mr. M. M'Clelland was the contractor. On entering the electric light station the first thing that commands attention is the three large powerful steam-engines, which have been entirely made and erected by a local firm—Messrs. Alex. Brown and Sons. Two of the engines were put in motion to drive the dynamos which lighted the city on Saturday evening with successful results. The engines are of a marine type. The fly-wheels are 8ft. in diameter, 24in. broad on face, and weigh about three tons each. On each flywheel there runs two 10in. belts for driving dynamos. All the engines have a separate jet condenser placed below the floor-level, so that at all states of the tide the river water can be used for steam condensation. The engines are controlled by Hartnell governors. The engines are to run at 150 revolutions per minute, and at this speed, with 125lb. per square inch boiler pressure, will indicate about 130 h.p. each, which is about 50 per cent. in excess of what is required. In the erection of the steam-engines in position and in the placing of the dynamos a large six-ton overhead travelling crane, erected by Messrs. Alexander Brown and Sons, was used. The boiler-house contains two boilers, either of which is sufficient to supply steam for the three steam-engines. The boilers are 26ft. long by 7ft. in diameter, made from the best selected boiler steel. The boilers, and all pipes, etc., carrying the boiler pressure, were tested by Messrs. Alexander Brown and Sons, in presence of Mr. Blake, up to a pressure of 200lb. per

Digitized by Google

square inch, and all certified as satisfactory. The economiser is placed behind the boilers in a specially-constructed chamber. All the work has been done in the high-class style which characterises the firm of Messrs. Brown and Sons. Messrs. Siemens Bros. supplied the dynamos and cables. There are six of the former, two pairs being used to supply the light and one pair being kept in reserve. The dynamos run at 750 revolutions per minute. There are 160 arc lamps of 2,000 c.p., and these can be added to without requiring extra plant, the engines and dynamos not being fully loaded. The representative of Messrs. Siemens Bros. is Mr. Collins, who has superintended the laying down of the entire electrical plant. He was assisted by Mr. Mittlehausen, of the same establishment. The arc lamps used are of the Brockie-Pell type, of which Messrs. Johnson and Phillips, of Charlton, London, are the sole manufacturers. The present installation in Derry consists of 160 lamps. The ornamental cast-iron carriers used are of Messrs. Johnson and Phillips's own design, and the lamps were put up by the firm's own men, under the supervision of their engineer, Mr. Ernest J. Clamp.

PROVISIONAL PATENTS, 1894.

MARCH 12.

5102. **A new or improved telephonic relay.** George Gillmore, 70, Market-street, Manchester.

5118. **Improvements in and connected with electro-locomotion on railways.** William Edwin Heys, 70, Market-street, Manchester. (Jean Jacques Heilmann, France.) (Complete specification.)

5157. **Improvements in apparatus for indicating the height of fluids in tanks or reservoirs by electricity.** Matthew Mawson and Arthur Stuart, Cornwall House, Humber-road, Blackheath, London.

5158. **Improvements in splice coverings for electric wires.** Thomas Jefferson Dewees, 45, Southampton-buildings, Chancery-lane, London. (Complete specification.)

5164. **Improvements relating to fittings for suspended electric lamps.** Adolph Hoffmann, 18, Buckingham-street, Strand, London.

MARCH 13.

5194. **Improvements in the method of and apparatus for starting and stopping electric motors.** Thomas Reginald Andrews and Thomas Preece, Borough Mills, Manchester-road, Bradford.

5203. **Improved electric-lit sights for night shooting, on sporting rifles and other guns.** Montague Herbert Galsworthy and Sydney Stuart Galsworthy, 33, Gloucester-gardens, Hyde Park, London.

5217. **Improvements in phonographs and appliances connected therewith.** Alfred Charles Brown and George Richard Neilson, 50, Old Broad-street, London.

5223. **Improvements in or connected with electric batteries.** Charles Percy Shrewsbury, Frank Lawrence Marshall, John Cooper, and John Lasky Dobell, 57, Chancery-lane, London.

5243. **Improvements in electric perforating pens.** Aaron Dabney Lewis, 323, High Holborn, London.

5253. **Apparatus for electric lighting, ventilating, etc., by means of storage batteries and dynamos driven from car axles or other power of varying speed.** William Lloyd Wise, 46, Lincoln's-inn-fields, London. (Isaac Newton Lewis, United States.) (Complete specification.)

5254. **Apparatus for electric lighting, ventilating, etc., by means of storage batteries and dynamos driven from car axles or other power of varying speed.** William Lloyd Wise, 46, Lincoln's-inn-fields, London. (Isaac Newton Lewis, United States.) (Complete specification.)

5271. **Improvements in or connected with electric railways.** Edward Holmes Brown, Norfolk House, Norfolk-street, London. (Complete specification.)

5273. **Improvements in closed conduits for electric railways.** Reginald Walter Barker, Monument-chambers, King William-street, London. (The Lawrence Electric Company, United States.) (Complete specification.)

5276. **Improvements in electric railways.** James Fulton Cummings and Eugene Mathew Engelman, 45, Southampton buildings, Chancery-lane, London.

MARCH 14.

5314. **Improvements in magnetic separators.** Septimus Leonard Anderson, Bank-buildings, George-street, Sheffield.

5340. **Improvements in the construction of electrical resistance coils.** John Ambrose Fleming, University College, Gower-street, London.

5359. **Improvements in electrical signalling and in apparatus therefor.** Charles Balbiani, 22, Glasshouse-street, Regent-street, London.

5363. **An improved form of alternating-current dynamo.** Thomas Barnet Grant, 15, George-street, Mansion House, London.

MARCH 15.

5449. **Improvements in connection with alternating-current dynamos working in parallel.** Guy Carey Fricker, 46, Lincoln's-inn-fields, London.

5417. **A method of and apparatus for electrically signalling or transmitting a communication in the event of a fire or conflagration.** James Thomas Cockerill and William Ellis Bennett, 2, Old Market-chambers, Yorkshire-street, Rochdale.

5433. **Improvements connected with the insulation of electric conductors of armatures or other encased, enclosed, or insulated electric conductors from which it is desirable to allow of the transmission of heat.** Henry Edmunds, 47, Lincoln's-inn-fields, London.

5474. **Improvements in electric arc lamps.** William James Davy, 40, Chancery-lane, London.

MARCH 16.

5508. **Improvements relating to the transmission of signals through submarine telegraph cables.** Alexander Muirhead, 124, Chancery-lane, London.

5509. **Improvements in the manufacture of submarine cables.** Alexander Muirhead, 124, Chancery-lane, London.

5531. **Improvements in dynamo supports for portable and traction engines with locomotive-type boilers.** Frederick John Burrell, 18, Fulham-place, Paddington, London.

5537. **Electrical deposition of zinc and alloys of zinc and apparatus therefor.** Richard Heathfield and William Stepney Rawson, 1, Leadenhall-buildings, London.

MARCH 17.

5579. **Improved solutions for the electric deposition, separation, and refinement of aluminium.** John Kirkwood, 87, St. Vincent-street, Glasgow.

5592. **Improvements in counterweights for electric light pendants and other similar purposes.** John Grubb and Wilson Henry Sturge, 12, Cherry-street, Birmingham.

5619. **Improved construction or arrangement of bridge or support for electric wires and in appliances for fixing or holding such wires in place therein.** Hugo Bartels, 166, Fleet-street, London.

5631. **Improvements in and connected with the electric lighting of trains and other vehicles.** Edwin James Preston and Arthur Bernard Gill, 77, Chancery-lane, London.

5637. **Improvements in electric accummulators.** Irénée Chavanne, 6, Bream's-buildings, Chancery-lane, London.

5643. **An improved telephone combination.** Sir Charles Stewart Forbes and the Domestic Telephone Company, Limited, 21, Finsbury-pavement, London.

5647. **Improvements in the manufacture of secondary coils for transformers.** August Schneller and William John Wisse, 46, Lincoln's-inn-fields, London.

5650. **A thermometric circuit closer.** Richard Pearson, 53, Chancery-lane, London.

NOTES.

Accumulator Works.—These works are to come under the supervision of inspectors appointed by the Home Secretary.

Royal Institution.—On Tuesday next, Prof. J. A. Fleming will begin a course of lectures on "Electric Illumination."

Institution of Mining and Metallurgy.—The president, Prof. A. K. Huntington, delivered his inaugural address last week.

Central London Railway.—The prospectus of the Central London Railway is about to be issued by the Exploration Company.

Explosion at Preston.—An explosion of gas has occurred in connection with the electric light mains of the electric supply company.

Society of Arts.—On Monday next, at 8 p.m., the first Cantor lecture on "Photometry," by Captain W. de W. Abney, C.B., F.R.S., will be delivered.

York.—In the new bank premises of the York branch of the National and Provincial Bank of England, provision is made for both gas and electric lighting.

The Coatbridge Station.—The Coatbridge station of the Scottish House-to-House Electricity Company, Limited, will be set in operation to-morrow (Saturday) by Lord Kelvin.

Electric Ploughs.—It is said that Messrs. Siemens and Halske are experimenting with an electric plough on the estate of Biesdorf, the property of Mr. Arnold von Siemens.

France and New Caledonia.—France has just been placed in direct telegraphic communication with New Caledonia by the completion of the cable between that colony and Australia.

Scarborough.—The theatre at the Scarborough Spa is to be lighted by electricity. The general adoption of the illuminant at the Spa is a matter for the future consideration of the committee.

Lighting of Liverpool Streets.—By the direction of the city engineer, Mr. H. P. Boulnois, two lamps lighted by electricity have been placed at the bottom of London-road at the junction with Lime-street.

International Telegraph Convention.—The British Ambassador in Paris has notified the Government of the French Republic of the adhesion of the English colony of West Australia to the International Convention.

Society of Engineers.—The next ordinary meeting of this society will be held at the Town Hall, Westminster, on Monday, April 2, commencing at 7.30 p.m. A paper will be read on "Gasholder Construction" by Mr. E. Lloyd Pease.

Electric Traction at Dunedin.—Mr. Webb, Melbourne, and Mr. Walker, Government electrician, of Sydney, are to report to the Government on the introduction of an overhead trolley system in connection with the Dunedin tramways.

Dundee Institute of Architecture, Science, and Art.—The third ordinary meeting of the institute for this session will take the form of a social gathering in the Victoria Art Galleries, Dundee, on Thursday next, April 5, at 6.45 p.m.

Electro-Harmonic Society.—The final smoking concert of the season, as stated in our last issue, will take place this (Friday) evening at the St. James's Hall Restaurant, Regent-street, W. The programme, which was given in our issue of the 23rd inst., is an excellent one.

Northern Society of Electrical Engineers.—This society will hold a smoking concert on Monday next, April 2, at the Palatine Hotel, Hunt's Bank, Manchester, commencing at 8 p.m. Members, who may take friends with them, are requested to assist in the entertainment.

Glasgow Corporation Station.—A paper on "The Corporation Electric Light Supply" was read last week before the members of the Institution of Engineers and Shipbuilders in Scotland by Mr. William Arnot, electrical engineer to the Corporation of Glasgow. The paper was illustrated by diagrams.

London County Council.—The Council propose to introduce this session a Bill relating, among other matters, to the expenditure of money on the electric lighting of the Victoria-embankment, the embankment gardens, and Waterloo and Westminster Bridges, and to the purchase of plant for electric light testing.

Telegraphy in the French Soudan.—The telegraph line between Sigueri and Kankan has been completed. This line will be continued to Keruane, and later on to Kissindougou, the most southern French post in the Soudan. A French paper demands a prolongation of the line, which now runs as far as Segu, up to Jenne, Mopti, and Timbuctoo.

Lighting of Tramcars.—The London Tramways Company are making experiments in the electric lighting of tramcars. The company for a few weeks have had the interior of one of their cars fitted with the electric light. Since Thursday of last week they have utilised the current for illuminating the roof of the car upon which the garden seats are placed.

Personal.—The Corporation of Kingston-upon-Thames, Surrey, have increased to £250 a year the salary of their borough electrical engineer (Mr. J. E. Edgcome), and have appointed him advising engineer to the Drainage Committee with regard to the machinery at the sewage works. Lord Kelvin, whose resignation of his Glasgow Professorship was the other day rumoured, has decided to hold his post till 1896, when he will celebrate his jubilee.

Underground Railways in Paris.—At a meeting of the French Council of Ministers, M. Jonnart, Minister of Public Works, presented a scheme for the construction of a metropolitan railway for Paris. The scheme provides for a series of underground lines which will connect the various terminal stations of the great railway lines. It is proposed to ask the Municipal Council of Paris to share with the State the guarantee under which the new railway will be constructed.

Royal Meteorological Society.—The monthly meeting of this society was held last week, Mr. R. Inwards, F.R.A.S., president, in the chair. Mr. W. H. Dines read a paper on the "Relation between the Mean Quarterly Temperature and the Death-rate," and a second paper on the "Duration and Lateral Extent of Gusts of Wind, and the Measurement of their Intensity." A third paper read was "On the Calculation of Photographic Cloud Measurements," by Dr. K. G. Olsson.

Lectures.—Mr. W. B. Sayers has lectured before the members of the Philosophical Society of Glasgow on "Dynamo-Electric Machinery, and Some of its Applications." Current was introduced from the city electric mains into the lecture hall, and used to give demonstrations with a dynamo, a motor, and electric lamps. At a meeting of the Sheffield Junior Engineering Society on Tuesday, a paper on "Gas *v.* Steam Engines for Factories

Digitized by Google

and Electric Lighting Stations" was read by Prof. W. H. Watkinson, of the Glasgow and West Scotland Technical College.

Electric Jib Crane.—An electric jib crane has been erected at the Chester Wharf, Pimlico, where Messrs. F. B. Cameron and Co. unload coal from barges in the Thames. The current is supplied from the mains of the Westminster Electric Supply Corporation. Calculations based upon a series of tests with a weight of 15cwt. of coal show that the efficiency of the crane, the maximum lifting power of which is three tons, stood at 78 per cent. This crane, which is capable of unloading about 200 tons of coal per day, was made by Messrs. Wimshurst, Hollick, and Co., of 602, Commercial-road, E.

Explosion at Bournemouth.—An explosion has taken place in a junction-box, and on the fact being reported to the electric lighting company, an examination of a box was made, but there was nothing to account for the explosion. Another box close by was opened, and when the iron lid of this had been removed, a spark at once made the defect visible. The explosion is attributed to an accumulation of gas in the box, the gas being fired by the electric spark. The Board of Trade was communicated with, and Major Cardew, the inspector who reported on a recent mishap in another part of the town, arrived and made an inspection on the spot.

An Exemplary Sentence.—A sentence, which should prove a severe deterrent, was passed at the Liverpool Assizes last week by Mr. Justice Day on Francis M. Conville, who was tried for swindling John Gardner out of over £50. The prisoner was formerly a bill-poster in the employ of a Liverpool quack, and he started in the same line when his former employer left. His chief methods of treatment were bleeding and an alleged electric belt. He charged fees up to 50 guineas, and the police stated that in three months last year he netted £800, and was known to make £3,000 or £4,000 a year. The accused was found guilty, and the judge sentenced him to five years' penal servitude.

Another Earl's Court Exhibition.—It is intended to hold at Earl's Court from May to October an exhibition of British industries. The principal object of the exhibition is to illustrate as far as possible the industries of Great Britain, with special reference to the advance made in methods of production and in new inventions during the past few years. A special feature will be made of the various industries which can be shown in actual operation. The buildings will be lighted by electricity, and the grounds will be illuminated by thousands of electric, gas, and Vauxhall-lights. The exhibits will be divided into seven sections—manufactures, mechanical engineering, machinery and electricity, agricultural, mining and metallurgy, science, fine arts.

Lighting of Suburbs.—The London correspondent of a Glasgow paper states that: "A powerful syndicate is to be formed, with the support of one of the Rothschilds, with the view of applying for and putting into operation provisional orders for lighting by electricity some of the large and fashionable suburbs of London. In the Metropolis there are 13 electric light areas, but only one of these (St. Pancras) is the result of municipal or corporate enterprise. All others are by private companies. A number of these supply residential districts—Kensington, Mayfair, St. James's parish. The others depend on the demand for business premises. The great demand, however, experienced by some of these companies supplying purely residential areas has suggested that the large suburbs would welcome the new light."

Communication between Lightships and the Shore.—In addition to the electrical connection established between the Kentish Knock Light-vessel and the shore, and to which reference was made in our last issue, telephonic communication has been formed between the North Goodwin Light-vessel and Ramsgate. In this case the distance is much shorter than that between the Kentish Knock and the shore, being only a little over five miles; but as this lightship practically commands the Goodwin Sands, her electric connection is likely to prove of much service in affording the means of giving information at the earliest possible moment of casualties in the vicinity of the sands. The arrangements for carrying the electric cable clear of the ship's moorings are in all respects similar to those adopted for the Kentish Knock, and described in our last issue. The electric cable is taken ashore at Dumpton Gap and then connected with the Ramsgate Post Office. The ships engaged in completing this second lightship were the Post Office cableship "Monarch" and the Trinity steamers "Vestal" and "Warden."

Charing Cross, Euston, and Hampstead Railway.—The prospectus is issued of the Charing Cross, Euston, and Hampstead Railway Company, which is authorised by its special Act of Parliament to construct and work an underground electric railway connecting Charing Cross with Euston and Hampstead, comprising a line about five miles in length, commencing in the Strand, at or near Charing Cross, passing underneath King William-street, Charing Cross-road, Tottenham Court-road, Hampstead-road, Haverstock-hill, and terminating at the junction of High-street with Heath-street, in close proximity to Hampstead Heath, including a branch from the Hampstead-road terminating at or near Euston Station, and forming a communication between that station and Charing Cross. Stations will be constructed at or near Charing Cross, Oxford-street, Euston-road, Euston Station, Mornington-crescent, Chalk Farm, Belsize-park, and Hampstead Heath. The issue is now announced of the authorised share capital of £1,416,000 in £10 shares. The application list opened yesterday, and will close on or before Tuesday next for town and country. The prospectus states that it is proposed to equip the railway for a 2½-minute service each way, with a seating capacity of 200 passengers per train, and it is estimated that the profits will be sufficient to pay over 6 per cent. on the share capital.

The Elongation Produced in Soft Iron by Magnetism.—Mr. S. J. Lochner deals with this subject in the *Philosophical Magazine*. He used for his researches an instrument resembling in its essential features a Michelson interferential refractometer of great sensibility, the elongation being measured by means of a mirror, and the limit of sensibility being lower than one-millionth of an inch. He found that the route by which a certain magnetising force had been arrived at affected the amount of expansion for that force, the expansion varying for rising and falling currents in a curve very similar in shape to the hysteresis cycle. His general results may be summed up as follows: They indicate that the expansion is a function of the ratio between the diameter and the length, and that the elongation varies directly as, possibly, the square root of this ratio. Also, that the expansion varies directly as the permeability. That the amount of magnetising force required to produce the maximum expansion, and the point of no expansion, depends on the ratio between the diameter and the length. That there are two maxima—one produced by increasing the current, and another by decreasing the current from the point which produced the first maximum. That the first contact gives more expansion than the second and following contacts; and, further, that these appear to

Digitized by Google

disagree among themselves, the expansion falling off with subsequent contacts. The paper is fully illustrated with tables and diagrams.

Lighting of the Houses of Parliament.—Despite the abnormal length of last session, and the consequent brevity of the periods of recess during which alone structural alterations can be carried out in St. Stephen's, the Office of Works succeeded in making considerable progress with the electric light extension during the year 1893-4. This work, which was commenced under Mr. Plunket's *régime*, is now approaching completion. The task of replacing gas by incandescent lamps without causing inconvenience to the army of officials, was one of no small difficulty. So far, the Office of Works have kept well within their estimate of expenditure. It was computed at the outset that the total cost of the installation would be about £12,000. The actual expenditure up to the end of the current financial year is £8,500, of which £1,600 represents the contribution for the last 12 months. The sum set apart for electric light extension in this year's Civil Service Estimates is £1,200. In view of the greater utilisation of the new illuminant, it was only to be expected that the charges for oil lamps, etc., would show a considerable diminution; as a matter of fact, the estimate for the coming year in this connection is £1,250 as compared with £1,375 in the year 1893-4. Curiously enough, there is an increase of £225 in the estimate for the supply of gas to the two Houses.

The Rating of Electric Lighting Undertakings. The financial progress which so many companies are making is beginning to excite the attention and cupidity of the rating authorities, with the result that assessments in some instances of a most unreasonable character are attempted to be put into force. We have previously directed the attention of our readers to this matter, and some further illustrations of the method have come to our notice. The Eastbourne authorities some time ago raised the assessment of the Eastbourne Electric Light Company from £150 to £795. No doubt some increase in the assessment was warranted by the progress the company had made, but Mr. Humphreys-Davies, of the Machinery Users' Association, advised that the large increase was altogether unjustifiable. The result of the appeal has been a reduction to £525, or about two-thirds. In another case, also conducted by the same association, the Preston authorities have now offered to reduce the assessment of the National Electric Supply Company, Limited, from £1,095 to £675, but this offer has been declined, and an appeal to quarter sessions is intended. As Preston is one of the most highly-rated towns in England, the aggregate rates amounting to nearly 8s. in the pound, the importance of the question will be easily seen, for as the rates are the first charge upon the undertaking, each increase of £100 in the assessment practically means adding £1,000 to the debenture debt if the latter can be raised at 4 per cent., or £800 if at 5 per cent.

Competition for Self-Contained Vehicles.—The proprietors of *Le Petit Journal*, Paris, are organising a competition of self-moving vehicles, to take place on June 1 next. The conditions are as follows: (1) the competition is to be international, vehicles of any country being admitted; (2) no condition is imposed relative to the motive power, which may be steam, electricity, gas, petroleum, or anything else; (3) the vehicles must be able to seat at least four people; (4) preliminary and eliminatory trials are to be made before the competition takes place—for the first of these trials the distance is to be 31 miles, to be traversed in three hours; (5) the preliminary trials are to take place on the roads from Paris to Mantes, Paris to Dreux, Paris to Beauvais, Paris to Gournay, etc.; (6) the first trial is to be made on the road from Paris to Rouen, *vid* St.-Germain, Triel, Meulin, Mantes, Vernon, Gaillon, and Pont-de-l'Arche, the distance being 78 miles; (7) the prize is to be given to the horseless vehicle which best combines the conditions of safety, commodiousness, and economy; (8) each vehicle during the preliminary tests is to carry the inventor or his representative, two members of the jury, and a consulting engineer. Applications will be received from competitors up to April 30, accompanied by a short designation of the vehicle and an entrance fee of 10f. (8s.). The first prize, named *Le Petit Journal* prize, will be 5,000f. (£200). There will be four other prizes respectively of the values of 2,000f., 1,500f., 1,000f., and 500f., say, £80, £60, £40, and £20.

Non-Magnetisable Watches.—The importance of non-magnetisable watches has considerably increased since the extensive use of electricity for the purposes of lighting and traction has made a strong magnetic field almost an ordinary incident of daily life. Of course, remarks the *Times*, watches that can be placed upon the poles of a powerful magnet without being affected have been known for some years, but it has not hitherto been found possible to make them go with sufficient accuracy to win a first-class Kew certificate. The hair-spring in such watches has to be made, not of steel, but of palladium—a metal which is so susceptible to variation of temperature as to make their going uncertain. This difficulty seems now to have been overcome by using an alloy of palladium. Messrs. S. Smith and Son, of the Strand, have been able to produce a non-magnetisable watch which has obtained the highest, or Class A, certificate at Kew, with 79·2 marks out of a possible 100, and was awarded the remarkably high number of 18 marks out of 20 for compensation for effects of temperature. Another non-magnetisable watch from the same makers has gained 19 marks out of 20 for the temperature tests, and its certificate is endorsed: "This watch was subjected to magnetic influence in an intense magnetic field, and its general performance was apparently unaffected thereby." The Kew Committee have shown their appreciation of the importance of non-magnetisable watches by instituting a special class for them and constructing apparatus to test them. With reference to this paragraph, Messrs. Curtis and Horspool, of Leicester, write that in October last a non-magnetisable watch made by them obtained a Class A Kew certificate, marked "especially good," with 81·2 marks out of a possible 100. For temperature compensation this watch gained 19·3 marks out of 20.

County of London and Brush Provincial Electric Lighting Company.—As will be seen from our advertisement columns, the County of London and Brush Provincial Electric Lighting Company, Limited, is inviting subscriptions for ordinary shares. The Company, which was registered in 1891 for the purpose of undertaking the supply of electricity in certain districts in London and in the United Kingdom, has obtained provisional orders, which have been confirmed by Acts of Parliament, for the united parish of St. James and St. John, Clerkenwell, the parish of St. Luke, Middlesex, the district of the Wandsworth Board of Works, including portions of Putney, Clapham, Balham, Upper Tooting, Tooting, Brixton-hill, and Streatham-hill, and the parish of St. George-the-Martyr, Southwark. In addition to these districts the Company will undertake the erection and equipment of power stations in provincial towns where municipal authorities have obtained provisional orders for the supply of electricity which they are prepared to transfer to a responsible company. The Company intends to exercise a

Digitized by Google

control over the general business and development of the provincial supply undertakings in which it will become interested. It is intended to at once commence work in St. Luke's, Clerkenwell, and in Wandsworth, whilst in the provinces a controlling interest is to be acquired in the local electric supply companies at Bournemouth, Dover, and Canterbury. Moreover, at Shrewsbury, Bedford, Weston-super-Mare, and other towns negotiations for electric supply are proceeding. The directors are Messrs. J. Bevan Braithwaite, jun., W. C. Braithwaite, F. W. Reynolds, Aymor H. Sanderson, F. Evance Savory, R. Percy Sellon, and B. H. Van Tromp. The capital of the Company is £800,000, but the present issue by the Electric and General Investment Company, Limited, comprises £200,000 in 20,000 ordinary shares of £10 each, of which 19,900 are now offered for subscription. The list of subscriptions will open on Thursday next, April 5, and will close at 4 p.m. on *the same day*.

The Pacific Cable Question.—In the course of an article on "The Colonies" the *Times* says the mission to this country of Mr. Robert Reid, the Victorian Minister of Defence, is drawing to an end, and Mr. Reid has expressed himself as on the whole well satisfied with what he believes himself to have achieved. The principal objects of his mission were three in number. One was to endeavour to facilitate the connection of Australia and Canada by means of a Pacific cable. With regard to the cable, initiative taken on the Canadian side and embodied in the proposals of Mr. Sandford Fleming has been met on the Australasian side by the sympathetic vote, recorded at the Postal Conference lately held in New Zealand, in favour of guaranteeing the interest at 4 per cent. upon a sum of £1,800,000 to be devoted to the construction of the cable. In the midst of these evidences on the part of the colonies of a genuine desire to draw the bonds of union closer, the Imperial Government has alone so far made no sign. To judge by its actions the matter appears to be one to which it is indifferent, and some perception of this attitude is to be noted in the developing caution of the colonial Governments. Naturally they desire to know what response they are to expect in the movement towards us. The vote of the Australasian Postal Conference was, in the case of one colony, given subject to the condition that the Imperial Government should join in the colonial guarantee. One of the three points which are to be definitely pressed upon the Imperial authorities is a request that the Imperial Government will consent to join in an Imperial and colonial guarantee of interest to a limited sum for the construction of a Pacific cable. With regard to this request, it may be said that to grant it is little more, in fact, than to make a formal expression of sympathy with the object of the scheme. The sum for which a guarantee of interest is to be asked is not to exceed £1,800,000. This represents at 4 per cent. a total amount of £72,000 a year, for which we are to make ourselves responsible in conjunction with the Dominion of Canada and the seven colonies of Australasia. Suppose that the scheme should be financially a failure and that we should be under agreement to pay in perpetuity as much as one-half of the guarantee, the military advantage alone of possessing a British cable to the antipodes would be worth securing at the price. If the scheme has even a fractional part of the public utility which is attributed to it, the public guarantee will be, after the first year or two, a liability only in name.

Recording Wattmeter for Arc Circuits.—The success which the Thomson wattmeter for incandescent circuits has experienced has prompted the General Electric Company to design a recording wattmeter especially for the measurement of energy used in groups of arc lights in commercial lighting, such as in stores, factories, halls, and the like. This meter, we gather from the *Electrical World*, is the outcome of 2½ years of careful investigation and experiment. Indeed, probably no other meter or instrument manufactured by the General Company has received more careful study than this meter. It is a true wattmeter, modified in its principles only to meet the change of conditions of arc light service. It is similar in construction to the well-known Thomson recording wattmeter, and has the same damping device—a copper disc and two permanent magnets. It has been designed on the lines of an arc lamp, so far as its location, etc., are concerned—that is to say, to be suspended from the ceiling by two brass rods fastened to a simple ceiling-board, and the same object is attained as in the suspension of arc lamps from the ceiling; the meter is inaccessible except to those who understand its manipulation. A special feature is the safety cut-out contained within the cover proper. The meter is designed to close immediately on possible trouble occurring within it, which might result in the burning out or breaking of the circuit. The cut-out serves to short-circuit the meter and cut it out, rendering trouble in the meter impossible. At the same time, it preserves the continuity of the circuit, and permits the lights to burn without interruption, an advantage sufficiently obvious. The connections of the meter are exceedingly simple. The connection blocks are at the top, the wires being brought first to the ceiling-board, then dropping to the meter. The two terminals farthest from the front of the meter are connected to the line through an absolute cut-out, the two front terminals being connected to the lamps in the house. So far as the operation of the meter is concerned, it makes no difference which wire is positive and which negative, though, of course, to have the lamps to burn correctly, attention will have to be paid to this point. No trouble will be caused if the lineman should make a mistake and connect the wires, which should go through the front terminals to the back and *vice versâ*; there will be no short-circuit or burning out. The meter will run backwards but register correctly, subtracting, instead of adding to, the sum on the dial. Careful tests show that the same accuracy can be expected on a minimum load as on a maximum, and this accuracy is of the highest.

Distribution of Motive Power in France.—The Marquis of Dufferin and Ava, in a despatch to the Foreign Office, encloses a report by Sir J. Crowe, commercial attaché in Paris, on the subject of the distribution of motive power to the dwellings of workmen in France. The information supplied by Sir J. Crowe may be summed up as follows: According to the returns, the Nord is still the most important department for motive power, as it utilises 132,000 horse, or nearly one-seventh of the whole power of France. The department of the Seine follows with 86,000 horse, Pas de Calais with 63,000. Next comes the Loire with 48,000; Seine Inférieure with 43,000; Saône et Loire with 42,000; Meurthe et Moselle, 38,000; Vosges, 32,000; Rhone, 26,000; Bouches du Rhone, 22,000. Neither at Lyons nor at St.-Etienne is there any distribution of power by compressed air, nor is there any application as yet at Lyons of electricity, but Lyons is preparing for establishing works on a large scale to produce, by means of a canal, a waterfall capable of yielding a force of 12,000 h.p., to be distributed in the shape of electrical energy in the dwellings of subscribers. Hitherto Lyons has had at its disposal steam motive power equal to 13,000 h.p.; 1,000 h.p. in addition is obtained by gas-motors, but very little of this is at the disposal of weavers, who want motors of small power, and having been unable till now to get them in the town, have been forced to emigrate

Digitized by Google

into the country. The promoters of the new canal, who obtained an Act of the French Parliament, hope to be able to meet the wants of the Lyons weavers by distributing, even to one loom, the power which at present is got by hand. They propose to do so by electricity, obtained by means of a weir at Jonage, above Lyons, which is to give the fall and motive power required. At St.-Etienne three electrical companies exist, from which motive power can be obtained. Their operations have been almost exclusively confined to lighting, but the Edison Company has already 28 subscribers, to whom a motive power of 36 h.p. is assigned. The Electric Company of the Loire, with power obtained from a fall of the Loire at St.-Victor, distributes motive power in the three communes of St.-Genest, Roche la Molière, and St.-Rambert. The number of its subscribers is 12, to whom power up to 7 h.p. is supplied. The Electrical Association of Lignon gets its power from the fall of Lignon, in the Haute-Loire, and has two subscribers for 6 h.p. and 2 h.p. in the communes of St.-Manlice and St.-Didier. It is apparent that St.-Etienne is only just beginning to develop what may become a large business in the distribution of motive power.

Electrolytic Action of the Return Current of Electric Railways.—A special report was recently presented by Messrs. G. W. Plympton and F. R. Lee, the board of commissioners of electric subways for the city of Brooklyn, N.Y., to Mayor Schieren regarding the corrosion of water-pipes, gas-pipes, and telephone cables by the return currents from the various electric railway systems of the city. The report is given as an appendix to the annual report of the commission submitted on December 15 last. The commissioners say: "The experience of Brooklyn is not notably different from that of Boston and Cambridge, Mass., Milwaukee, Wis., Columbus, O., Indianapolis, Ind., and Hamilton, Ont. In each of these cities similar corrosion has been detected, and in none is there any doubt as to the cause. It is known to be due to the imperfections of the means provided by the trolley companies for the conveyance of the electrical current back to the generator. It was at first supposed that the rails would be sufficient, but the current declines to take that route exclusively. The remedy of the evil will have been applied when the trolley companies shall have provided an adequate route for the electric current now discharged into the rails. It was at first reasonably supposed that the rails would afford a sufficient path. Upon the failure of this plan a copper connection to carry the current by the joint was tried. In most cases this expedient failed of complete success, except where the copper bond had unusual dimensions." The commissioners then give the result of several ways of connecting rail joints by copper wires, etc., continuing as follows; "A better way to ensure the conduction of the current is, doubtless, to make the car rail continuous by welding. This method will be employed on the new trolley line soon to be built in the southern part of the city. The most complete solution of the problem is afforded by the double trolley by which the return current is provided for by an overhead wire similar to the one for the outgoing current. But it is to be hoped that it will not be necessary to resort to this method." Some notes of experiments obtained through Mr. I. H. Farnham, electrician of the New England Telephone Company, and relating to the early experience in Boston, are then given, the commissioners concluding as follows: "The conclusions fairly drawn from these notes and from our own experience is that considerable injury is being done to underground pipes and cables, and that it will continue along the lines of the trolley roads (except where the elevated railway extends above them) until better methods of returning the current to the generator are put in practice. The electricians of the several trolley roads are fully aware of the situation, and have speedily applied means of prevention in localities where the corrosion had been detected; but it is doubtful if the method of final cure of the difficulty has yet passed the experimental stage."

The Oldham Central Station.—The ceremony of setting the plant in operation has just been performed. The streets provided with the electric light are the chief business streets in the town, and contain also the principal public buildings, Town Hall, art gallery, public library, etc. Steam is provided by two Lancashire boilers working at a pressure of 120lb. per square inch. Coal can be brought into the station either from the Lancashire and Yorkshire Railway, which adjoins it, or from the street, as may be found most convenient. The engine-room adjoins the boiler-house. Four dynamos have been provided, each driven direct by a Willans engine. The total horse-power provided is 320. A switchboard stands at one end of the engine-room, the space beside the engine being utilised for stores, and at the other end of the engine-room is an engineer's room and lavatories, etc. In the space below these offices a condenser and air-pump worked by a separate engine are placed, and there is a reservoir for condensing water between the boiler-house and the railway. The engines are arranged so that they may be worked either with or without condensation. Above the office is additional store accommodation, and above the engine-room is a battery-room, in which is placed a battery of about 60 cells of 500 ampere-hours capacity. The station is so designed and constructed that the offices can be readily removed to its eastern end when extension becomes necessary. The plant mentioned above is sufficient for the simultaneous lighting of about 2,500 incandescent lamps of 8 c.p. each, or their equivalent, ample reserve being provided in case of any machines requiring repair or overhaul. Judging from the experience of other towns, 2,500 lamps alight at one time corresponds to a total of about 5,000 lamps actually installed. As the area to be supplied is a small one and fairly close to the station, and as there will be very long hours during which the amount of lighting will be excessively small, a low-tension system of the simplest possible kind has been adopted—namely, a two-wire system in which the current is distributed at 105 volts. The mains are bare copper carried upon stoneware insulators in concrete troughs or conduits, carried under the footpaths. Where the roadways are crossed, or where there is not room under the footpaths for a concrete conduit, the mains are laid as insulated cable, carried in cast-iron pipes or casings. The conduits are so arranged that fresh mains can be pulled into them as may be required without any opening up of the roads or footways beyond the lifting of the covers upon the manholes or service boxes. The system of supply is arranged throughout so that at any future time it may be possible to change it into a three-wire system with a minimum of alteration, and without pulling up the footways or roadways. The batteries will be used partly as reserve, but mainly for the purpose of supplying current during the hours of minimum demand, which in a place like Oldham will often be very long. The batteries will be charged by the dynamos during the hours when they must in any case work to supply current to the circuits. By allowing them afterwards to discharge, the whole station can be shut down at night, and often in the morning also, so as to economise expenditure in wages and also in fuel.

(Continued from page 344.)

THE ELECTROMOTOR.

It is useful to have a few of the most characteristic features of motors collected together, so that the different conditions of working that there are between a shunt and series wound motor may be easily perceived. The following refer to motors that are run from off constant-pressure mains.

The Shunt-Wound Motor (1) can be used only on a constant-pressure circuit; (2) the current in the field coils remains constant whatever the speed or the load may be; (3) the current in the armature coils decreases as the speed increases, or as the load decreases; (4) the torque or pull of the armature is proportional directly to the current in the armature; (5) the speed remains nearly constant with varying loads; (6) not suitable for starting with dead load on, or for mounting a grade..

The Series-Wound Motor (1) can be used on either constant-pressure or constant-current circuits, but chiefly is used on the former; (2) the current in the field coils

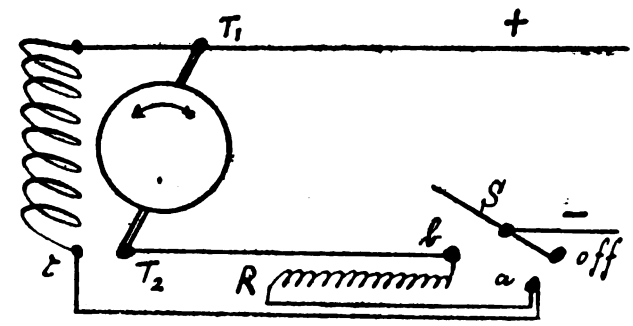

Diagram I.

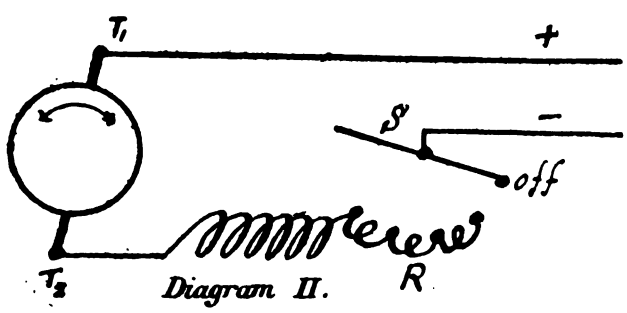

Diagram II.

FIG. 43.

decreases when the speed increases, or when the load decreases; (3) the current in the armature coils decreases when the speed increases, or when the load decreases; (4) since the same current flows through both field and armature coils, therefore the torque of the armature will vary (within certain limits) with the *square* of the current flowing; (5) the speed will vary inversely as the load; (6) suitable for starting with dead load, or in mounting grades.

The E.M.F. that is developed by either a dynamo or a motor is proportional to the speed of the machine, and the strength of the current in the armature coils measures the amount of pull to which the armature is subjected. The product of pressure into current gives electrical power, and, similarly, the product of speed and pull gives mechanical power, so that generally, and in particular with reference to series-wound machines, pressure may be said to correspond with speed and current with mechanical pull. In the case of a dynamo, it is the armature current that strives to drag round the magnetic field in which it revolves; and in the case of a motor, it is the magnetic field that exerts a pull on the armature current and so causes the armature to revolve. The torque of a revolving shaft is obtained by multiplying the pull by the radius of the shaft, and the power transmitted by the shaft is obtained by multiplying the pull in pounds by the peripheral speed in feet per minute. Thus, if P be the force or pull acting on the shaft, and r be its radius in feet, and n = the number of revolutions per minute, then $P \times 2\pi r n$ = foot-pounds of work done per minute, and dividing by 33,000 gives us the horse-power.

Starting and Stopping Motors.—In starting electromotors, a little more caution is required than in starting dynamos, if such a statement can be made; the reason for this is that the armature coils may get badly burnt if the requisite starting resistance is not operated in the right way. If by accident, however, the supply current is switched right on to the armature on starting the machine, it will be found that the safety fuse will blow before any serious damage will be done; but that is not the only thing that will happen. A short-circuit of this kind will always burn or damage the commutator and brushes to a greater or lesser extent, according to whether the fuse is quick-acting or not. Diagram I. of Fig. 43 illustrates a common way of connecting up a shunt-wound motor on to a constant-pressure circuit, the motor being belted to a ventilating fan, which it drives at a constant speed.

The starting resistance is made of spirals of iron wire mounted on an iron frame. This resistance is indicated by R in the diagram. On the top of the frame is the switch, S, having three contact studs. The first stud is marked "off," and the switch is shown in that position. The stud *a* goes to the negative end of the shunt coils, denoted by the letter *t*, this end of the shunt coils being separated from the negative brush. The stud *b* is connected to the negative brush by means of the terminal T_2. The positive main of the supply circuit is joined on to the positive terminal, T_1, while the negative main is joined on to the switch, S, the resistance, R, being connected across *a* and *b*. There are thus three terminals in the motor—two large ones to which the positive and negative brushes are connected, and one small one to which the negative end of the shunt coils is attached. Having oiled up the machine and set down brushes with a slight *backward* lead, it can be started by moving the switch on to stud *a*; this inserts the resistance, R, in the armature circuit, and connects up the shunt coils direct to the supply mains, so then the field current is at a maximum, while the armature current is large, yet reduced to safe limits. At the end of a few seconds the motor has got up a good speed; then the switch is moved on to stud *b*. This cuts out the resistance in the armature circuit, but at the same time inserts it in the field circuit, thus allowing the armature current to increase and decrease the field current. The motor now quickly arrives at full speed, and in so doing the back pressure generated allows only a small current to flow, sufficient to enable the motor to do its work. When stopping the motor, the switch can be at once thrown back to the "off" position.

Diagram II. shows the connections for running a series-wound motor off constant-pressure mains. The motor is started by inserting the whole of the resistance, R, into the motor circuit; then, as it gets up speed, the resistance is gradually taken out by moving the switch forward. The more the resistance that is taken out, the faster will the motor run. To stop the motor, gradually insert the resistance again.

(To be continued.)

CENTRAL-STATION WORKING WITH GAS-ENGINES AND ACCUMULATORS.

Some little time ago (see the *Electrical Engineer*, 8th December, 1893, p. 533) we touched upon the question of employing gas-engines and accumulators for central-station work, and dealt briefly with the manifest advantages that are obtained in this way with regard to levelling down the peak in a daily load diagram, since the generating plant may not only be worked almost continually at maximum output, but is, in addition, of smaller capacity and consequent first cost. One considerable difficulty, however, lying in the way of any extensive adoption of this otherwise excellent system is that the size and power of gas-engines have hitherto been rather limited, involving thereby the use of inconveniently small station units. This objection seems now to be overcome, or is in process thereof, and the

Digitized by Google

system generally is being advocated with great warmth in many quarters. Amongst these, as might be expected, perhaps, from a business point of view, the accumulator-makers are prominent, and we note that one of them, the Accumulatoren-Fabrik Company, of Hagen, Westphalia, has gone to the length of issuing a pamphlet dealing with the subject, and containing a number of illustrations and details, some of which we reproduce herewith.

Speaking generally upon the subject, it is, of course, well known that the daily external load of any electric lighting station varies enormously, the heavy output being really only required for two or three hours, at say 6 o'clock p.m., whilst all the rest of the day the plant is nearly idle. In the illustration appended (Fig. 1) the ordinary

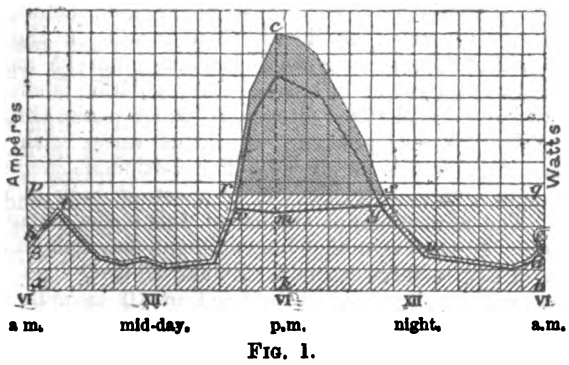

Fig. 1.

load curves are shown in the usual way with a peak reaching its maximum towards 6 p.m. The plant must, of course—in a direct-running station—be equal to the maximum output, shown by the ordinate, ck. By employing accumulators, however, the total capacity of the generating plant at work may be reduced to an amount represented by the ordinate, pa; the plant being driven continuously at full load, so that its output curve is a straight line, $prsq$. The surplus energy stored up at times of light load—from p to r and from s to q—is drawn upon during the time—from r to s—when the load is supernormal.

The Hagen Accumulator Company has followed this plan in drawing up several schemes for town-lighting; these are based upon the use of sub-stations of various sizes and capacities, and in each case estimates are given of the amounts necessary both for capital expenditure and working costs. Some brief notice of these schemes may be taken with advantage.

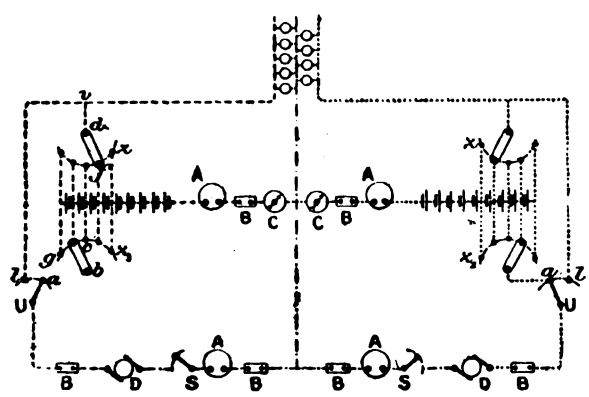

Fig. 2.

One of them provides for the erection of two sub-stations, in any specified district, each of 240 h.p. capacity. For this output three gas-engines would be erected, of 120 h.p. each. Two are supposed each to drive a continuous-current generator, whilst the third is held in reserve. The number of lamps which could be incandesced at the same time from such a station would amount to 7,570, each giving, that is, 16 c.p. at 50 watts. The two stations, therefore, could together run 15,140 such lamps; or assuming not more than two-thirds alight at once out of the total installed, at least 22,710 lamps could be wired. The maximum radius of distribution of each sub-station is given as being about 800 yards, with a working E.M.F. of 200 volts on the three-wire system, and allowing for a drop of 10 per cent. in the voltage owing to line resistance.

The three generating dynamos are of shunt-wound type, giving 697 amperes at 110 volts, and made to charge two batteries of accumulators with a capacity of 4,628 ampere-hours, the rate of charge being 662 amperes and of discharge 1,060 amperes. Figs. 2 and 3 represent the arrangement of distribution adopted with two and three generating units respectively; the methods used are so sufficiently clear from the illustrations that descriptive details are almost unnecessary.

The estimates drawn up by the Hagen Accumulator Company for financial outlay required upon a project of the type detailed herein are divided into four groups, showing respectively the capital outlay, working expenses,

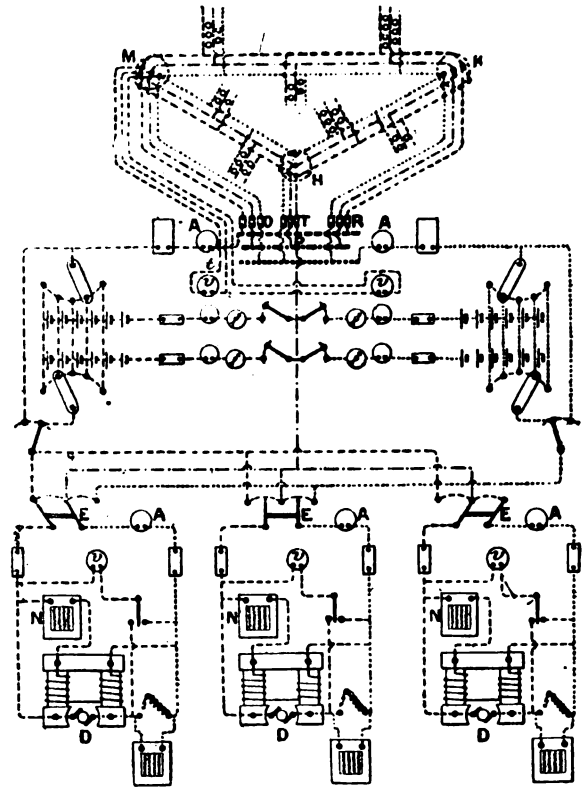

Fig. 3.

probable revenue, and the resulting net profits. In detail they are roughly as follows:

A.—Capital Outlay.

Land and buildings	£7,110
Gas-engines	8,167
Dynamos	5,099
Accumulators	15,682
General station work—switchboards, lighting, etc.	5,775
Distributing mains	31,829
Miscellaneous	350

B.—Working Expenses.

Salaries and wages	1,095
Gas (650 litres per horse-power hour)	2,584
Oil and acid	250
Repairs	280
Miscellaneous	911

C.—Working Results.

Output of electric energy	567,750 kilowatt-hours.
Receipts, at the rate of 10d. per kilowatt-hour, less 5 per cent. discount	£21,574
Total expenditure, allowing 1½ per cent. on buildings, 7½ per cent. on plant, and 3 per cent. on mains, for sinking fund	9,138

From these figures it is stated that with a sinking fund of 4 per cent., and allowing for 3½ per cent. interest, the net profit is 13 per cent. and 9 per cent., according to the price obtained per unit of energy distributed.

SWITCHING GEAR FOR DIRECT AND ALTERNATE CURRENT DYNAMOS.

In the course of the description given in our last issue of the new central station of the Sheffield Electric Light and Power Company, reference was made to the automatic switching gear and electrical governor carried by each

Digitized by Google

exciter and to the synchronising pillars (one of which is provided for each alternator), which are equipped with complete switching gear. We now proceed to describe and illustrate these devices which have been invented by officials of the Brush Electrical Engineering Company, Limited. Fig. 1 shows the automatic switching gear devised by Mr. Raworth for use with continuous-current dynamos or exciters. It is applicable in all cases where two or more continuous-current dynamos or exciters are arranged to work in parallel on a common circuit. The apparatus consists of a cast-iron pillar which carries the switching gear and instruments, which are usually an ammeter and a voltmeter. The switch closes automatically when the dynamo attains a voltage equal to that existing in the station mains, whilst it opens automatically when the dynamo ceases to generate current. In order to bring another dynamo into circuit, a weighted lever is fixed up and the engine started. To take a dynamo out of circuit steam is shut off. This switch pillar is placed near the dynamo so that the instruments may be in the view of the attendant in turning on steam. It is claimed that this automatic switching gear entirely prevents accidents from (1) closing switch when dynamo is unexcited or not giving full E.M.F., from (2) closing switch when polarity of dynamo is reversed, and (3) from the current coming back on dynamo and burning down the fuses.

FIG. 1.—Automatic Switching Gear for Direct-current Dynamos.

FIG. 2.—Interlocked Switching Gear for Alternators Working in Parallel.

In Fig. 2 is represented interlocked switching gear devised by Mr. Raworth for use with alternators working in parallel. This apparatus greatly facilitates the working of alternators in parallel, and its general appearance is shown in the illustration. It will be seen that the main switch lever is in the middle, the field switch on the left, and the synchroniser switch on the right. The interlocking gear is arranged so that the main switch cannot be closed until the field switch is closed and the field fully excited, also not until the synchroniser switch is closed. When the main switches are closed the field switch cannot be opened, and the main switches are locked by shutting off the synchroniser switch. The main switches break through water and oil, and are practically sparkless under all conditions. The complete apparatus includes two main switches, one field switch, one synchroniser switch, one synchroniser, one synchroniser voltmeter and two lamps, one main voltmeter, one main ammeter, and one field ammeter. It is claimed that this interlocked switching gear entirely prevents accidents from (*a*) closing main switch when the alternator is unexcited or not giving full E.M.F., and from (*b*) the opening of the field switch when the main switch is closed.

Another invention of Mr. Raworth comprises interlocked switching gear for main feeders for continuous or alternating currents. This apparatus, which is shown in Fig. 3, takes the form of a cast-iron pillar which carries the main switches, fuses, ammeter, and voltmeter, regulating gear, and interlocking machinery. In the base of the pillar, where the leads enter, there is a switch for disconnecting the upper part of the pillar and for establishing the circuit, in order that the instruments, fuses, and switches may be examined and repaired without cutting off the feeder. There are three fuses fixed on the top of the pillar, any one of which may be put in circuit by turning the right-hand handle, but this handle cannot be moved unless the main switch be open. Double-pole switches are fixed below the fuses, and are actuated by the central handle, which is locked by a trigger, which must be released before the switch can be opened or closed. The handle on the left actuates the disconnecting switch, but it cannot be moved unless the main switch be open. The regulation is effected by two hand wheels fixed on a shaft, which passes through the pillar. The regulating apparatus varies with the system of generation employed. For continuous current it consists of a variable resistance, or a set of back E.M.F. cells. The advantages of the use of this feeder pillar are obvious. In the event of a fuse failing, a new one can be put in circuit in three seconds. Should all three fuses fail, a new set can be inserted by hand in 10 seconds. By means of the disconnecting switch any part of the gear can be examined and repaired without any possibility of shock. As the handles are all interlocked no mistakes can be made.

Among other inventions brought out by Mr. Raworth

FIG. 3.—Interlocked Switching Gear for Main Feeders.

may be mentioned a return-current fuse, for use with alternators in parallel, and a universal electrical contact. The former renders the parallel working of alternators perfectly safe, because the fuse will melt only with return current—that is to say, the fuse cannot be melted whilst energy is being transmitted from the alternator to the mains, but should the alternator from any cause fail to give its full E.M.F. the fuse will immediatly act and cut it out of circuit. The importance of this invention cannot be over-estimated, as with plain fuses the possibility of a total extinction is always present. For instance, if three alternators be working in parallel and one of them fail, then the other two have to supply current for the outer circuit and sufficient additional current to burn down the fuses of the disabled alternator. Under these conditions all the fuses would go simultaneously, or the fuses of the two working alternators might melt without cutting off the disabled alternator. With the new return-current fuse this cannot happen, as it will not act with excess current in the right direction, but only with current in the wrong direction. The principle of the return-current fuse is as follows: two paths are provided, one through the fuse and the other through an accelerator, which gives the current a bias to

Digitized by Google

select the latter path, but the accelerator has a contrary effect on a return current, forcing it through the fuse. With regard to the universal electrical contact, this presents large surfaces of contact which remain parallel or at the same angle to each other under varying degrees of pressure. The contact-piece is a casting, and is made for use with bar or plug connecters, either parallel or taper. For taper connectors the contact surfaces are arranged at such an angle that the bar or plug will stick between the contact faces, but may be removed by the exertion of a very slight force. The surface of contact is fully four times the sectional area of the metal. Sparking contacts are provided for preventing deterioration of the faces. The contact-pieces are standardised for 250, 500, and 1,000 amperes, each having a large margin.

The Brush Electrical Engineering Company have also introduced an automatic transformer switch invented by Mr. Mordey. This switch has been designed with the view to avoid loss of power during the daytime or periods of light load by automatically removing transformers from circuit when not required for use. It is of very simple and safe construction, and has been developed with a special view to being left for long periods without attention, and having been subjected to long and severe tests is recommended to central-station engineers. The Brush-Geipel automatic regulator is another invention, being a development of the well-known combination of the Brush automatic regulator and Geipel relay. In this improved form of the regulator the variable shunt resistance consists of a pair of carbon plates immersed in water to an amount depending upon the resistance required. The plates are hung from a lever, the movement of which is controlled by an electromagnet receiving its impulses through the relay. The movements of the lever vary the extent of immersion of the plates and produce the required regulating effect in the fields of the dynamo. The apparatus is now made for use with all standard sizes of Brush dymamos. It is very simple, is adjusted without difficulty, and is easily kept in order.

Mr. Mordey has also invented automatic rocker gear for Brush dynamos. This is intended to take the place of the ordinary hand-adjusted rocker used for carrying the brushes of the Brush dynamos. It is controlled by an electromagnet in the regulator circuit, and is moved forward or backward according to the load. For instance, if the number of lamps on the circuit of the dynamo be altered, or if the speed of driving it be varied from any cause (the current being maintained constant by the Brush-Geipel regulator), by this new device the brushes are brought into the position of best collection. This movement has hitherto been done by hand. This rocker is useful, not only in cases where the load or speed is subject to variation, but also where the number of lamps is fixed, as it effects the small variations of position, which even in this case are desirable, and so lessen the wear of the commutator and the amount of attention necessary.

POLYPHASE TRANSMISSION.*

BY CHARLES F. SCOTT.

Alternating-Current Problems.

When alternating current was introduced for lighting it presented many new problems to the electrical engineer. Numerous difficulties and dangers were predicted by the theorist, but in ordinary service most of these have fortunately lain dormant. These difficulties are apt to appear, however, when alternating-current work is attempted on a large scale. The introduction of larger units, heavier currents, higher potentials, or power service are apt to increase the effects of self-induction and capacity so that they will now demand careful consideration. The impetus which electrical engineering is receiving from the introduction of the polyphase system, which brings with it large units and long distances, naturally directs attention to the general problem of alternating-current transmission and distribution.

* Paper read before the National Electric Light Association, Washington.

A complete and exhaustive solution of this problem is by no means a simple one, and the attempted solutions generally lead to formulæ and diagrams which are possibly even more perplexing than the phenomena. If even the electrician who devotes all his energy to new problems can scarcely keep abreast of the times, it is not surprising that the practical engineer and station manager become perplexed and confounded at the apparently erratic phenomena observed in practice or described in print. Theoretical articles appear on variation in wave form, harmonics, so-called Ferranti effects, increased resistance in conductors with alternating currents, hysteresis, peculiar magnetic

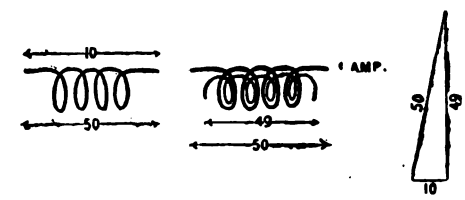

Fig. 1A. Fig. 1B.

circuits, resonance, oscillations, lag, capacity, self-induction. Many of these articles, although evidently intended to be of service in engineering, show apparently no adequate appreciation of the practical bearing and relation of the subjects treated. Consequently, the average engineer becomes bewildered and perplexed, and concludes that theoretical explanations are of little value to the practical man. There are, however, many points of great practical importance which admit of fairly simple statement and explanation. The particular element to be considered in the present paper is the transmission circuit.

Experiments Illustrating Self-Induction.

One of the fundamental characteristics of alternating-

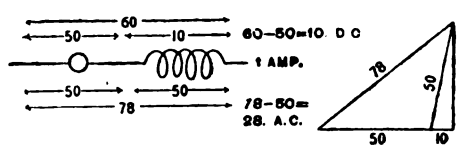

Fig. 2.

current working is self-induction. The effect of self-induction is most readily shown by a simple experiment. A wire having a resistance of 10 ohms may be wound in a coil. Ten volts will send a continuous current of one ampere through this coil. An alternating current of a certain frequency will require 50 volts for producing one ampere through the same wire (Fig. 1A). In the diagrams the numbers above the circuit are for continuous current, and those below are for alternating current. If a one-ampere 50-volt lamp be placed in series with the coil and a current of one ampere be passed through the two in series, the E.M.F. required for continuous current is 10 volts on the coil and

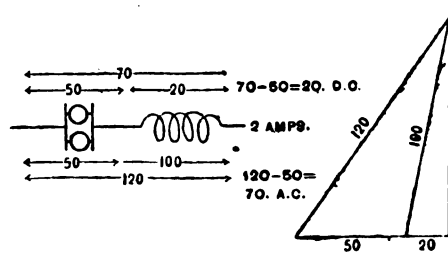

Fig. 3.

50 volts on the lamp, or 60 volts across the circuit, and the E.M.F. required for alternating current is 50 volts across the coil and 50 volts across the lamp, which gives, not 100 volts, but 78 volts measured across the two in series (Fig. 2). If two lamps be placed in multiple and connected in series with the coil, two amperes will require for continuous current 20 volts on the coil and 50 volts on the lamps, or 70 volts across the circuit. For alternating current the E.M.F. on the coil is 100 volts, and on the lamps 50 volts, and on the circuit across the two in series the E.M.F. is 120 volts (Fig. 3).

Digitized by Google

The two lamps which are in multiple may be placed in series with a second coil so proportioned that an E.M.F. of 50 volts will send one ampere alternating current through the combination, and a continuous current of one ampere would be caused by 35 volts. This combination may be treated as a unit, and may be used to replace the single lamp in the above test (Fig. 2). If this combination be placed in series with the first coil, the E.M.F. required for sending the continuous current through the circuit will be 10 volts on the coil and 45 volts on the circuit. If the alternating current of one ampere be sent through the

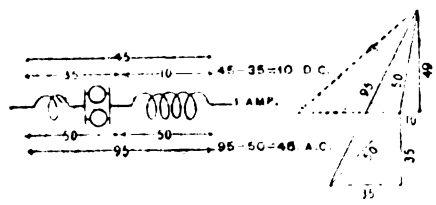

FIG. 4.

circuit, 50 volts will be required across the combination and 50 volts across the coil, the same as with the single lamp, but the E.M.F. across the circuit is no longer 78 volts, but has increased to 95 volts (Fig. 4).

The important facts to be noted in these experiments are (1) that the sum of the alternating E.M.F.'s on the elements in series is greater than that required on the terminals; (2) that the alternating E.M.F. for supplying the lamps in series with a coil is greater than the continuous E.M.F.; and (3) that the difference between the two becomes greater as the number of lamps is increased (Figs. 2 and 3). It is also to be noted (4) that if the same alternating current be supplied through a coil, first to a lamp alone, and then to a combination including lamps and a coil, a higher E.M.F. is required when the combination is used (Figs. 2 and 4).

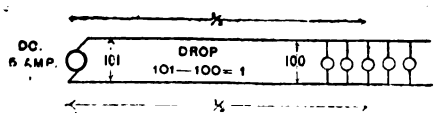

FIG. 5.

These relations, which seem rather perplexing, may be illustrated in a very simple way by diagram. In the case of the coil alone, in which 50 volts are required for producing one ampere alternating current and 10 volts for one ampere continuous current, these two E.M.F.'s may be represented by the hypothenuse and one side of the familiar right-angle triangle. The remaining side represents the counter E.M.F. in the coil. If a second wire had been wound in this coil in parallel with the first, it would be found that when one ampere is passing there is an E.M.F. on the terminal of the second, or idle wire of 40 volts (Fig. 1B). This E.M.F. is caused by

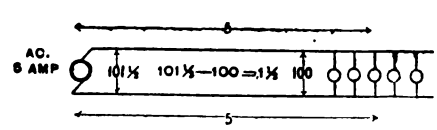

FIG. 6.

the field produced by the alternating current. An equal E.M.F. is, of course, induced in the wire carrying the current, as the two wires occupy virtually the same position. This counter E.M.F. is seen to correspond with the third side of the triangle. Suitable measurements would show that this counter E.M.F. occurs later than the current through the coil, and that its maximum value occurs when the current is passing through its zero. This relation is shown in the diagram by the 90deg. relation of the lines representing counter E.M.F. and the volts required for sending continuous current through the line.

SELF-INDUCTION IN CIRCUITS.

An ordinary circuit may be considered as a choke coil in which there is a single turn. The action in this case is very similar to that illustrated above with a coil of many turns. The effect of self-induction, in a circuit, may be most readily understood by some simple diagrams. A current of, say, five amperes is delivered at 100 volts over a circuit of one-fifth of an ohm resistance. The self-induction of the circuit is such that five amperes generate a counter E.M.F. of 10 volts. Both continuous and alternating currents are used, and the generator E.M.F. is in each case adjusted to give 100 volts at the load.

The load consists first of five incandescent lamps. A coil of high self-induction is then added, which increases the current from 5 to 5·1 amperes. One of the lamps is then cut out and replaced by coils of such a self-induction as to give a total of five amperes. Then all the lamps are cut out, and coils substituted of such a number as to take five amperes at 100 volts. The E.M.F. required on the generator and the resulting drop, or difference of E.M.F. at the

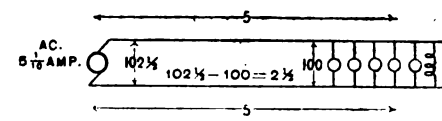

FIG. 7

dynamo and at the load, are given in the diagrams and in the following table:

	Continuous current.	Alternating current.			
	Fig. 5.	Fig. 6.	Fig. 7.	Fig. 8.	Fig. 9.
Current in line	5	5	5·1	5	5
,, ,, lamps	5	5	5	4	0
,, ,, coils.....	0	0	1	3	5
E.M.F. on load..... ...	100	100	100	100	100
,, ,, line	1	10	10	10	10
,, ,, generator ...	101	101·5	102·5	106	110
Drop—total	1	1·5	2·5	6	10

It is to be noted that with exactly the same circuit for supplying five lamps with the same amperes at the same E.M.F., there is an increase of drop between generator and load when continuous current is replaced by alternating current. This drop is much less than the volts required

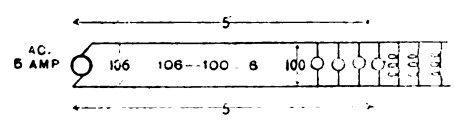

FIG. 8.

for sending the alternating current through the line, and it, moreover, increases enormously as the load becomes even slightly inductive. Thus, when the current is increased only 2 per cent. (from 5 to 5·1 amperes, Figs. 6 and 7), by the addition of inductive load to the lamp load, the increase of drop due to self-induction is increased from ½ per cent. to 1½ per cent., or an increase of threefold. When the load consists of four lamps, and coils are added in multiple to take a total of five amperes, or the same as that taken by the five lamps from the generator, the drop is four times the drop when five lamps alone are in circuit. If the remaining four lamps be re-

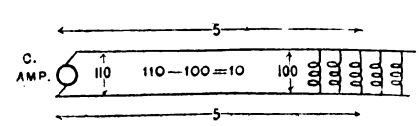

FIG. 9.

placed by coils, the drop does not increase in proportion, but from 6 to only 10 per cent. The effect, therefore, of a slight self-induction in the load causes a much greater proportional drop than the presence of a large self-induction. A counter E.M.F. of 10 per cent. is not at all likely to occur in a 100-volt line carrying small current. The figures given, however, serve as an illustration of the percentage variations which are liable to occur in other parts of the system.

DROP IN CONTINUOUS AND ALTERNATING CIRCUITS.

The word "drop" in continuous-current calculations has a perfectly well-defined meaning. In the case of the five lamps which takes five amperes at 100 volts through a circuit of one-fifth of an ohm, as illustrated in Fig. 5, the drop is (1) the difference between the E.M.F. at the generator and at the lamps, or one volt, which is 1 per cent.; (2) it is the E.M.F. required for sending the current through the line.

Digitized by Google

This is equal to the current multiplied by the resistance, and is the E.M.F. which would be required for sending the current through the line if the load be short-circuited; (3) a drop of 1 per cent. means also that the energy lost in the line is 1 per cent. of that delivered by the generator; (4) a loss of 1 per cent. in the line also signifies that the energy delivered is 1 per cent. less than supplied by the generator.

In alternating-current work the same uniformity does not exist; for example, in the experiments with the same five lamps and the same line (1) the generator pressure was 101½ volts, or ½ per cent. higher than that of the lamps; (2) the E.M.F. required for sending a current through a line short-circuited is 10 volts, or 10 per cent.; (3) the energy lost in wires is $C^2 R$, or five watts, which is 1 per cent. of the energy when five lamps are supplied. If four lamps and low-resistance coils are connected to the circuit, the energy delivered is, say, 400 watts, and the loss is 1¼ per cent.; (4) if the coils alone are supplied, and their combined resistance is equal to that of the circuit, or one-fifth of an ohm, then the losses in load and line are equal, and the actual line loss is 50 per cent. The apparent energy at the generator is 550 watts (110 volts and five amperes), and the apparent energy delivered is 500 watts (100 volts and five amperes), so that the apparent line loss is 9 per cent.

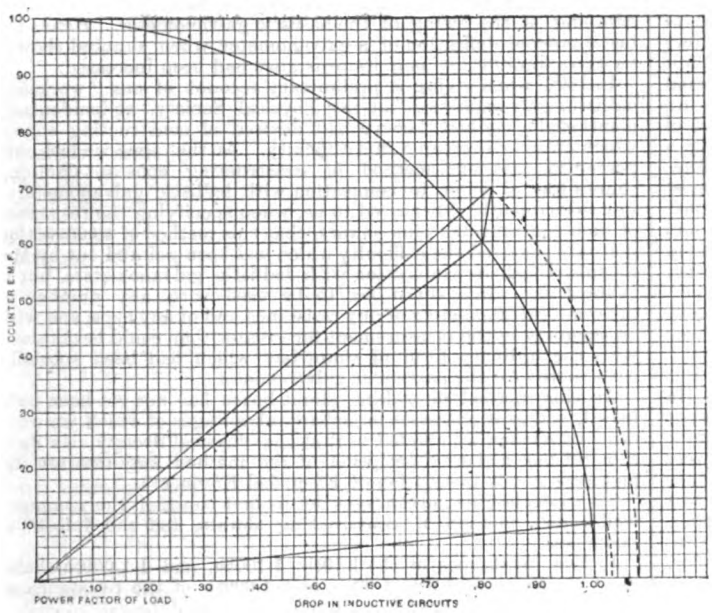

FIG. 10.

It is therefore evident that the several elements commonly referred to as drop or per cent. loss with continuous current are so modified when alternating current is used that it is possible for no two of them to have the same value. Moreover, with alternating current none of these elements may have the same per cent. value as that for continuous current on the same circuit.

LOSS AND REGULATION.

The two vital factors in the line are loss and regulation. The losses are $C^2 R$, and should be expressed in watts or horse-power, or as a per cent. of the energy delivered to the line. The practical point in regulation is the difference in E.M.F. at the generator and at the load. When these two factors are known, it is generally immaterial what E.M.F. might be required for sending current through a short-circuited line. The word "drop" is applied to the difference in E.M.F. between the generator and the load. The regulation is generally expressed in per cent. of generator E.M.F., but in this paper the E.M.F. at the load will be considered 100 per cent., as this is the element to be kept constant while the E.M.F. of the generator is variable, depending upon the load and other elements.

The regulation, or drop in the alternating-current circuit, is dependent largely upon the counter E.M.F. of the line. The factors which practically determine the counter E.M.F. of the line are size of wire, distance between wires, length of circuits, frequency, and current. Mr. A. E. Kennelly has given very complete curves (American Institute of Electrical Engineers, April, 1893) for determining the impedance of pole lines. The impedance factors given may be used for finding the current through a given line which is short-circuited at one end when the E.M.F. and frequency are known. The impedance factor of the line for supplying five lamps, described above, is 10, as the alternating E.M.F. is 10 times the continuous E.M.F. for the same current when the line is short-circuited. The word "drop" is applied in Mr. Kennelly's article to the volts required for overcoming impedance in a circuit, and the impression that this is the same as the drop in continuous-current circuits was not corrected in the paper, nor was this most practical point raised in the discussion. The relation between impedance and loss was, however, demonstrated mathematically in a communication after the meeting. The figures given in connection with the foregoing diagrams show very clearly that a circuit having the same impedance may have a drop between the generator and the load of from 1½ to 10 per cent., depending upon the character of the load. Impedance, therefore, does not determine regulation.

FIG. 11.

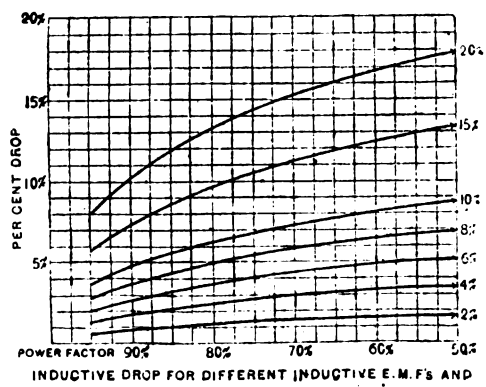

FIG. 12A.

CALCULATION OF DROP IN ALTERNATING CIRCUITS.

The regulation of a circuit is in general determined by two elements: the counter E.M.F. of the circuit and the self-induction of the load. The counter E.M.F. of a line depends upon the size of wire, the distance between wires and increases directly as the length of the circuit, the current and the alternations. The counter E.M.F. of a line has been calculated for a number of cases which are likely to occur in practice, and the results are given in Fig. 11. The drop or difference of potential between generator terminals and the load terminals due to the counter E.M.F. of the line, depends, as has been shown, upon the self-induction of the load. The latter is best expressed by a power factor, or a factor by which the product of the amperes and volts giving the apparent energy must be multiplied to give the true power in watts. The power factor for incandescent lamps is 1·00, or the apparent energy is equal to the true energy. The power factor for converters loaded with incandescent lamps is usually over ·90. The factor for unloaded converters varies from ·50 to ·80, and in open magnetic circuit converters—notably the "hedgehog"—the factor may be as low as ·05. The drop due to self-induction on the line (which, plus the ohmic drop, will give approximately the total drop) corresponding to various power factors of the load is given in Figs. 12A and 12B.

(To be continued.)

INSTITUTION OF ELECTRICAL ENGINEERS, Mar. 29.

Mr. ALEX. SIEMENS, President, in the chair.

At last night's meeting of the Institution the following candidates were balloted for:

Members.—Proctor, Charles Faraday, the Edison and Swan Company, Limited, Ponder's End, N.

Associates.—Benest, Francis Edward, 30, Cromwell-grove, West Kensington, W.; Davis, Clement Frederick, 75, Gipsy-hill, Upper Norwood, S.E.; Jones, John William, 13, Dornton-road, Balham, S.W.; Wardroper, W. F., 5, Windsor-terrace, Bedford.

Students.—Browning, Walter Buchanan, Faraday House, Charing Cross-road, W.C.; Duddell, William, Kensington Infirmary, Marloes-road, Kensington; Jones, Herbert William, Faraday House, Charing Cross-road, W.C.; Leigh, Frederick Augustus, 6, George-street, Huddersfield, Yorks.; Macfie, James Mathieson, M.A., Faraday House, Charing Cross-road, W.C.; Merritt, Francis Henry, Faraday House, Charing Cross-road, W.C.; Wade, Francis Richard, Gothic House, Beeston, Notts.

After the customary formal business had been transacted, the balance-sheet for 1893 was brought forward, but in view of the discussion on Mr. Mordey's paper and two additional communications to be read during the course of the evening, the **Chairman** proposed that the balance-sheet be taken as read. This was seconded by **Mr. Rawlings** and carried.

The adjourned discussion upon Mr. Mordey's paper was then resumed.

Major-General Webber expressed regret at not having heard the discussion at the previous meeting, but he had read—when they were published—the remarks then made, and had felt greatly struck with the extremely ingenious analogy brought forward by Mr. Mordey to express in physical language the interaction of two alternators running in parallel. He only wished to express one criticism upon the paper, which was to say that he felt sorry Mr. Mordey had not given more details of actual working of alternators in parallel, instead of (or in addition to) his laboratory experiments. That this would have proved of great value and interest, General Webber showed by citing a curious instance of parallel running in the City of London Company's stations, the data upon which Mr. Mordey would be most capable of supplying. In this case, the alternators coupled electrically were in two different stations—one at Bankside and the other at Wool-quay, 2,500 yards distant by cable measurement. The former is a Mordey-Victoria 100-kilowatt machine, driven by a Brush vertical engine at 167 revolutions; the latter a Thomson-Houston 130-kilowatt alternator, driven by a Marshall engine at 170 revolutions. Yet these two machines had been worked for more than 12 months in parallel most successfully.

Captain Sankey gave some additional information respecting the Thames Ditton experiments alluded to by Mr. Mordey. He did not agree with Mr. Raworth as to "hunting" in the governor being the real and only cause of pulsations in the Sunbeam lamps used as resistance; but thought, with Mr. Mordey, that they were caused by efforts to synchronise. He had measured the resistance of the lamps, and found it to be 35 ohms each when cold, this being reduced to 17 ohms with a current of 4·5 amperes passing. He concluded by expressing a wish to see the experiments continued by Mr. Mordey, and made that gentleman a sporting offer. If Mr. Mordey would send a couple of 30-kilowatt alternators down to Thames Ditton, his company would carry out any tests desired, for early publication.

A written communication from Prof. Forbes (who is now in America) was read by his secretary. It consisted almost wholly of a mathematical examination into the parallel working of machines, and did not attempt to deal with many of the questions raised. Prof. Forbes, however, wrote hurriedly, and promised further remarks later on.

Prof. Ayrton gave it as his opinion that the usual methods hitherto employed for synchronising alternators when it is desired to run them in parallel, were cumbersome and useless. He showed by means of a diagram how comparatively easy it is to gauge the exact moment of synchronism by putting the test appliance on the high pressure side; and advocated the use of any ordinary electroscope, say, for instance, one of the common foil-leaf type. This is connected to the two machines—foils to one, container to the other—a very fine connecting wire or conductor being also used to join the two machines direct. As the potential varies from maximum to zero, the period of divergence in the foil leaves becomes slower and slower, until at the moment of synchronism it is *nil*.

Mr. Mordey, in replying to the discussion, said that Mr. Raworth had been under the disadvantage of not having read the paper before the meeting, and that he had therefore probably made a remark which he would not have otherwise done as to the pulsation effect being entirely mechanical. The speaker thought it might have been entirely mechanical, but it might also have been electrical. He had stopped at the pulley of the dynamos, and would leave it to Mr. Raworth to proceed further and settle the matter with Mr. Sankey as to the hunting or otherwise of governors. Mr. Scott had emphasised the question of the steady running of engines in regard to his experience at Deptford. With regard to the spur-wheel analogies, the author was quite aware that all analogies must fail somewhere. He had put forward the analogy of spur wheels for driving and alternate working in a general and popular sense of giving some idea of what took place. He did not quite agree with the conclusion at which Mr. Kapp arrived at on the subject. The question really lay between good and bad regulation, and he agreed with Prof. Thompson that flexible teeth were necessarily weak. The machines necessary for good working in central stations were those which had a constant or nearly constant E.M.F. If they took a machine such as Mr. Kapp had referred to, and excited it for full E.M.F. and no load, and suddenly switched a load on, the volts would go down. He was of the same opinion as Mr. Kapp as to a margin of power, but he did not think that such a margin ought to be obtained by the use of devices which prevented machines from doing work. Prof. Thompson had mentioned parallel working with a common steam supply, without individual governors. The author, who referred to remarks made by himself some time ago on this point, and which supported what the professor had said, observed that the method was sound enough, although engineers might object on the score of steam consumption. Concerning Mr. Sankey's remarks, the hunting could not have been due to a change of load in the experiments mentioned, because there was no load on the machines.

Mr. A. Siemens, in a few remarks, brought the discussion to a close.

The following paper was then read:

A UNIVERSAL SHUNT-BOX FOR GALVANOMETERS.

BY W. E. AYRTON, F.R.S. (PAST-PRESIDENT), AND T. MATHER (ASSOCIATE).

Several years ago Mr. Latimer Clark drew attention to the fact that when shunts were used with a ballistic galvanometer in the comparison of the capacities of condensers, the results were inaccurate if the multiplying power of the shunts were assumed to be the same as those employed with steady currents; shortly afterwards the matter was investigated mathematically by the late Mr. Hockin, and he showed that the inaccuracy was caused by the change which the application of the shunt produced in the damping of the swing of the ballistic galvanometer. Hence the instantaneous deflection of a galvanometer when shunted showed an extra diminution, as if its resistance had been increased.

In 1892, when giving a preliminary account of our "workshop ballistic galvanometers" at the Physical Society, we incidentally mentioned a method that we had devised of constructing shunts which entirely overcame this difficulty. At that time we had only perceived that our method of constructing constant-damping shunts was of value in connection with ballistic galvanometers; but subsequently it occurred to us, when specifying the resistance of such constant-damping shunts, that this method of construction not only removed the difficulty which had been pointed out by Mr. Latimer Clark in connection with ballistic galvanometers, but it enabled the same shunt-box to be used with any number of different galvanometers of any resistance and of any type, and with an accuracy in the measurement far greater than could be obtained with the ordinary form of shunt-box which had been specially constructed for the particular galvanometer.

As this method of making shunt-boxes has not yet been published, and as it possesses important advantages of which we were not aware when we alluded to it at the Physical Society, we have thought that a short description of the method may interest the members of the Institution of Electrical Engineers.

To appreciate its advantages let us first consider the common, well-known method of constructing shunts, and the defects it possesses.

1. The resistances of the 1-10th, 1-100th, and 1-1,000th shunt must have exactly 1-9th, 1-99th, and 1-999th of the resistance of the galvanometer; therefore, if the resistance of the galvanometer be 1,000 ohms, for example, the shunts must have 111·1, 11·11, and 1·111 ohms resistance; hence we must construct the 1-1,000th shunt accurately to the one-thousandth of an ohm if we wish it to be correct to even 1-10th per cent.

2. But the galvanometer is wound with copper wire; we are therefore at once met with the difficulty as to what wire we ought to employ in winding the shunts. If we use German silver, platinoid, manganin, or any substance of low temperature coefficient for the wires of the shunt coils, their resistances may be quite constant, but a rise of 10deg. C. in the temperature of both the shunts and of the galvanometer will make an error of 4 per cent. in the resistance of the former relatively to that of the latter. If, on the other hand, we wind the shunts with copper wire, then, since the shunts are not inside the galvanometer case, it is very difficult to ensure, from the readings of thermometers, that there is not a difference of some 2deg. or 3deg. between the mean temperature of the shunt-box and of the galvanometer, so that the resistances of the shunts may easily be 1 per cent. wrong relatively to that of the galvanometer. In fact, except in the rare case when the galvanometer as well as the shunts are wound with German silver, manganin, or other wire of low temperature coefficient, it is useless spending time making accurate adjustments of the resistances of the shunt coils as ordinarily constructed.

3. Even if the resistances of the shunts be exactly 1-9th, 1-99th, and 1-999th of the galvanometer, they act as if they did not allow 1-10th, 1-100th, and 1-1,000th respectively of the charge in a condenser to pass through the galvanometer when used ballistically.

4. Lastly, for each galvanometer there is needed a separate set of shunts.

All these defects arise from the fact that the method hitherto adopted of varying the current through a galvanometer while the current in the main circuit remained the same, has consisted in varying the resistance of the shunt to the galvanometer. If, however, we leave the shunt to the galvanometer untouched, and instead vary the current through the galvanometer by varying the point of attachment of the main leads, we remove all these difficulties at once.

Digitized by Google

A shunt-box constructed in this latter way is seen in Fig. 1. The terminals A and B of the shunt-box are permanently connected respectively with the terminals of the galvanometer, G, while the terminals B and C of the box are connected with the two main wires which lead the current up to, and away from, the galvanometer and shunt. The ends of a coil of any resistance, r ohms, are permanently connected as shown, and at points in this coil corresponding with $\frac{r}{10}$, $\frac{r}{100}$, $\frac{r}{1,000}$ ohms permanent connections are made with the various blocks of the shunt-box as illustrated.

Then, whatever be the resistance of this coil, r, compared with the resistance of the galvanometer, g (either or both of which may therefore be unknown), it is easy to show that if G amperes be the current flowing round the galvanometer when a plug is placed into the hole marked d, it will be $\frac{G}{10}$, $\frac{G}{100}$, and $\frac{G}{1,000}$ amperes respectively when the plug is put instead into the holes marked c, b, a respectively, provided that the current in the main circuit remains constant—the condition which is, of course, assumed to be true in the ordinary use of shunts. Or, if a definite quantity of electricity flow into or out of a condenser in the main circuit, and Q coulombs be the quantity of electricity that flows round the galvanometer when the plug is in the hole marked d, $\frac{Q}{10}$, $\frac{Q}{100}$, and $\frac{Q}{1,000}$ coulombs will be the quantities that flow round the galvanometer when the plug is put into the holes c, b, and a respectively, and the deflections will correspond with these quantities.

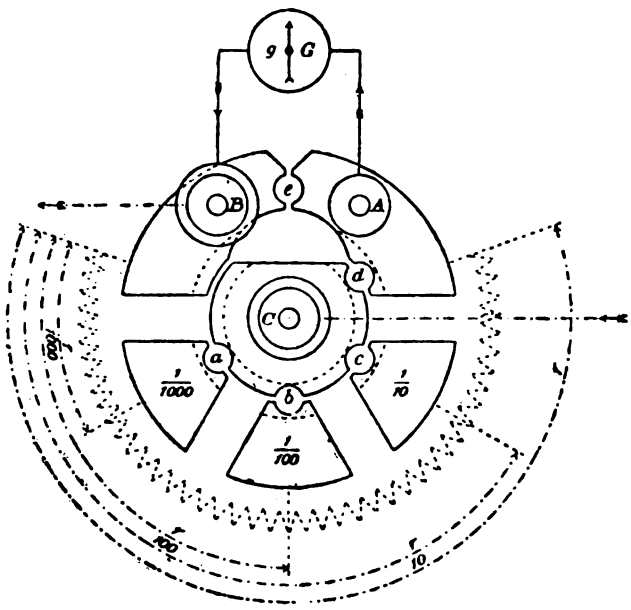

FIG. 1.

For let the constant current in the main circuit be called A: then when the plug is in hole d, the galvanometer current equals

$$\frac{r}{r+g}\text{ A, say G;}$$

when plug is in hole c, the galvanometer current equals

$$\frac{\frac{r}{10}}{\frac{r}{10}+\left(\frac{9}{10}r+g\right)}\text{ A, or }\frac{G}{10};$$

when plug is in hole b, the galvanometer current equals

$$\frac{\frac{r}{100}}{\frac{r}{100}+\left(\frac{99}{100}r+g\right)}\text{ A, or }\frac{G}{100};$$

when plug is in hole a, the galvanometer current equals

$$\frac{\frac{r}{1,000}}{\frac{r}{1,000}+\left(\frac{999}{1,000}r+g\right)}\text{ A, or }\frac{G}{1,000}.$$

Similarly, if K be the number of coulombs flowing into, or out of, a condenser in the main circuit, and p K, or Q, be the number of coulombs that flow round the galvanometer when the plug is put into the hole marked d, it may be proved that, since the resistance of the galvanometer plus that of the shunt is constant, and therefore the damping is constant, the quantities of electricity that will flow round the galvanometer when the plug is put instead into the holes marked c, b, and a respectively, are $\frac{Q}{10}$, $\frac{Q}{100}$, $\frac{Q}{1,000}$ coulombs.

Hence, the galvanometer may be wound with copper or with any other wire; a single set of shunts may be made of manganin wire, and be accurately sub-divided into exact numbers of ohms, fractions of an ohm being unnecessary with our system; the galvanometer may have any resistance and be at any temperature, provided it is constant while a set of tests is being made—then the sub-division of a steady current or the sub-division of an instantaneous rush of electricity into parts having the ratios of 1, $\frac{1}{10}$, $\frac{1}{100}$, $\frac{1}{1,000}$, is effected with great accuracy.

Stock shunt-boxes, ready wound for use with any galvanometer, in the measurement of steady currents or of instantaneous rushes of electricity are exhibited on the table.

The arrangement of shunt-box illustrated in Fig. 1 may be regarded as possessing one defect—viz., that the whole current flowing in the mains cannot be sent round the galvanometer without disconnecting the main wire from the terminal C, and connecting it instead with the terminal A. To save the trouble of having to do this, and to enable every combination to be made by simply shifting the plugs, we sometimes construct the blocks of the shunt-box as seen in Fig. 2. When one plug is placed and left in the hole marked h, and a second plug is placed in one or other of the holes marked d, c, b, or a, we obtain exactly the results already described in connection with the box seen in Fig. 1. Placing, however, one plug only in the hole marked f, the entire current flowing in the mains circulates round the galvanometer. If a plug be placed in the hole f, and another in the hole j, the galvanometer is short-circuited—a result obtained by placing the two plugs in the holes marked d and e in Fig. 1. The arrangement shown in Fig. 2 has the further advantage that it is possible, by putting a single plug into the hole marked j, to disconnect one terminal of the galvanometer from the circuit without breaking the circuit. This method of connecting is convenient to employ when taking the zero with a very sensitive galvanometer, for in that case it may happen that, although the galvanometer is apparently short-circuited through a very low

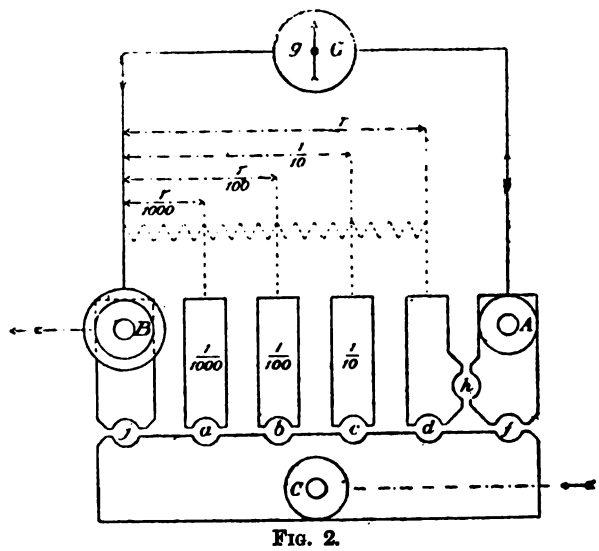

FIG. 2.

resistance, enough of the main current, although but an extremely small fraction, passes round the galvanometer to produce a small deflection.

When, however, r is more than about 10 times as great as g, the simpler form of shunt-box illustrated in Fig. 1 is sufficient for ordinary purposes; for, although by merely shifting the plug with this type of box, it is impossible to send a greater current round the galvanometer than $\frac{r}{r+g}$ A amperes, where A is the current in the mains, this value of G, being more than $\frac{10}{11}$ A, is sufficiently near A for ordinary purposes.

Of course, whatever be the value of r, whether large or small compared with that of g, the current that flows round the galvanometer when the plug is put into the poles marked c, b, and a respectively, is exactly 1-10th, 1-100th, and 1-1,000th of its value when put into the hole marked d. The only advantage that is gained by making r large compared with g is that $\frac{r}{r+g}$ A, or G, the unit current, becomes then practically equal to A.

The method of using shunts above described has, then, the advantage that it enables the same shunt-box to bo used with any galvanometer of any resistance, whether ballistic or not; but it does more than that, for a consideration of our method of varying the point of attachment of one of the mains, instead of varying the resistance of the shunt itself, shows that any ordinary resistance-box can be employed as a shunt with any galvanometer, and the fractions of the current that pass round the galvanometer and through the shunt respectively can be read off at once, without any calculation and without a knowledge of the resistance of the galvanometer, to a far higher degree of accuracy than is possible with a set of shunts specially constructed for the particular galvanometer in the ordinary way.

By employing this device we also find that great simplification and cheapening of cost is effected in the employment of a d'Arsonval galvanometer with shunts of platinoid or manganin sheet for the measurement of electric currents over a wide range.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" *can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—*

	3 months	6 months	12 months
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements should be made payable to C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."*

BOUND VOLUMES.

Vol. XII. of new series of "THE ELECTRICAL ENGINEER" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

LONDON REFUSE.

After the developments—or perhaps we should say convulsions—which were manifested not so very long ago in the Elmore companies and kindred financial circles, we almost began to hope that the field was cleared of those who pull the wires and make the puppets act in such wise as to draw liberal contributions from open-mouthed and empty-headed onlookers.

Doubtless the wily promoter of companies could well afford to "lie low" for a while, instead of prevaricating on high and in public; but for some reason—either because a slight improvement in the money market shows that there is more readiness to invest, or else because lack of funds makes it necessary to concoct some fresh scheme—still another sample of the bogus company is trotted out under the guise of "electrical inventions," as though that blessed word "electricity" were able always to prove an admirable and infallible nostrum for the financial *prestidigitateur*.

Under any other title the scheme of the London Refuse Steam Generator and Electrical Power Corporation, Limited, would prove no whit better investment for widows and orphans, whilst as it is, such an appellation is almost enough in itself to condemn the enterprise unheard. There may be, and doubtless are, exceptions to the rule, but in at least nine cases out of ten the amount of sinfulness in the promotion of a new company varies in strictly direct ratio to the length of the company's title. When one comes to examine closely into the stated objects, conditions, and prospects, the preliminary adverse judgment thus formed is, to put it mildly, confirmed through and through, finally, once and for ever. We have not hitherto commented in any way upon the extraordinary prospectus, and statements therein contained, with which the guileless and silly-headed public has been favoured within the last few weeks; the details of the scheme, the lack of strong support from men of any real standing, the absurd pretensions brought forward, were all so obvious that we expected no other results than a pleasant little time for those engaged in promoting the enterprise so long as the bubbles could be blown, and a nice little bill for someone to pay after the funeral—preferably, we should hope, the wire-puller at the back of the whole business.

If, however, there be the least chance of any disposition on the part of the public to invest a few pounds, or even a few pence, in helping to pay £400,000 in cash *or shares* to those interested in developing the Livet patents, then any criticisms we may pass upon the scheme from a technical and common-sense point of view will perhaps serve a useful purpose in restraining such a waste of good money. The Livet patents may be sound, and capable of maintaining their own in a court of law: we do not deny it, though if they occupy that enviable position they are, in a sense, unique. In such a case they would have an undoubted value—how great a value depends entirely upon the extent to which they hold a monopoly of appliances suitable for the efficient and economical destruction of house and other town

Digitized by Google

refuse. We believe such monopoly to be absolutely and wholly non-existent; and, in addition to this, we are confident that not only have better contrivances been a matter of history for some years, but hardly a month passes by without some improvement in methods or machinery. At the present time there are as many "systems" of efficient dust destructors as fingers on the hands, yet none of them can be said to have come into extensive use, and certainly have never been priced at figures fabulous or otherwise.

We have neither space nor inclination to follow out here all the mis-statements and misprints of the prospectus. That has already been done to advantage by a well-informed section of the daily press. We can, however, express ourselves strongly upon the fact that not a single engineer of repute will be found to say a word in justification of the claims made in the prospectus. Mr. Edwin E. Glaskin, M.A., S.C.E. (whatever these letters may mean), may be a capable engineer, but he is unknown when compared with Bramwell or Kennedy, and, speaking without any disparagement, we cannot accept his assertions as to steam trials confessedly of an imperfect nature. Chance statements made by engineers and technical papers appear to be dragged in as expressing approval of the scheme when really dealing with the matter in a general fashion: whilst the figures as to cost of plant, working expenses, probable profits, etc., are presented in the usual attractive and glittering form. It may seem quite correct and proper for an ignorant investor to see reports dealing with temperatures of feed-water and flues, pounds of water evaporated, and so forth (why not also give the state of the stoker's pulse, or the humidity of surrounding atmosphere?): but if this sort of thing is meant to appeal to the initiated, complaint must not be made if the latter say that the title of the company might with greater fairness be "London Refuse, Unlimited."

The sooner it is tumbled into one of its own destructors and turned into "steam of 250,000 c.p." the better for the community and world at large. At present one can only say that a possibly useful appliance in the shape of a boiler and furnace having somewhat novel features has been made the means of attempting to draw huge sums from the public in return for prospects of an extremely doubtful nature.

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

ELECTRIC TRACTION ON ROADS.

SIR,—In the *Electrical Engineer* of January 25, 1889, you treated of the "red flag clause," and stated that the question was brought forward at the last session of Parliament, 1888, and that the Act was interpreted as only applying to fuel-consuming vehicles; special mention was made of electrically-propelled carriages.

Again, the Inland Revenue department issue a notice to the effect that licenses must be obtained, etc.: "Carriages drawn by two or more horses or mules, or to be drawn or propelled by mechanical power."

I am much interested in the subject, and will give you details of trial of carriage shortly.

I have not seen letter to the *Times* referred to; naturally, I look at electrical papers for electrical subjects. If I cannot run my carriage in England it must go to Paris or Madrid, where every encouragement is being thrown out and no legal obstacles exist.—Yours, etc., C. R. G.

Birmingham, March 26, 1894.

[Our correspondent will doubtless be interested in the competition on this subject referred to in our "Note" columns.—ED. *E. E.*]

THE BRUSSELS MUNICIPAL ELECTRIC LIGHT STATION.

THE INCEPTION OF THE STATION.

The Municipal Council of Brussels have for several years had under consideration the question of lighting the town by electricity. It was for some time undecided whether to introduce a municipal supply or to grant a concession to a company, but eventually it was resolved to adopt the former course. As a result of this decision, a general specification was prepared in April, 1891, and tenders were invited from different quarters for a complete scheme, comprising both public and private illumination. The system to be introduced was not specified, but full details of the proposed method were required, together with particulars of the estimated working expenses. At the same time it was notified that the contractor selected to carry out the enterprise would be required to undertake the working of the station for two years, and would be liable to heavy fines in the event of the actual working expenses during that period exceeding the estimates. The schemes submitted included both alternating and direct current systems, and the municipality selected a three-wire low-pressure distribution method worked in conjunction with accumulators. On December 5, 1892, the India Rubber, Gutta Percha, and Telegraph Works Company, of Silvertown, and Persan-Beaumont, represented in Belgium by Mr. Boty, were entrusted with the execution of the contract, on the understanding that, or far as possible, all machinery, etc., should be constructed in Belgium, and that the whole of the contract should be completed in eight months after the site for the station had been placed at their disposal.

The site selected for the central station was that occupied by the old church of St. Catherine, Rue Melsens, in the lower part of the town, adjoining the main boulevard, and this ground, with the church and buildings upon it, was handed over to the company on February 13, 1893. The work of demolition was commenced on the same day, and this, together with the excavating work for foundations—which necessitated the removal of about 7,000 cube yards of earth, and the clearing away of the massive foundations of the old church—occupied a period of about 10 weeks. Eventually, in the middle of May, the construction of the new buildings was commenced by the contractor, M. La Barre, acting under the instructions of M. Devreux, the architect, and of the company's resident engineer, Mr. Stuart A. Russell.

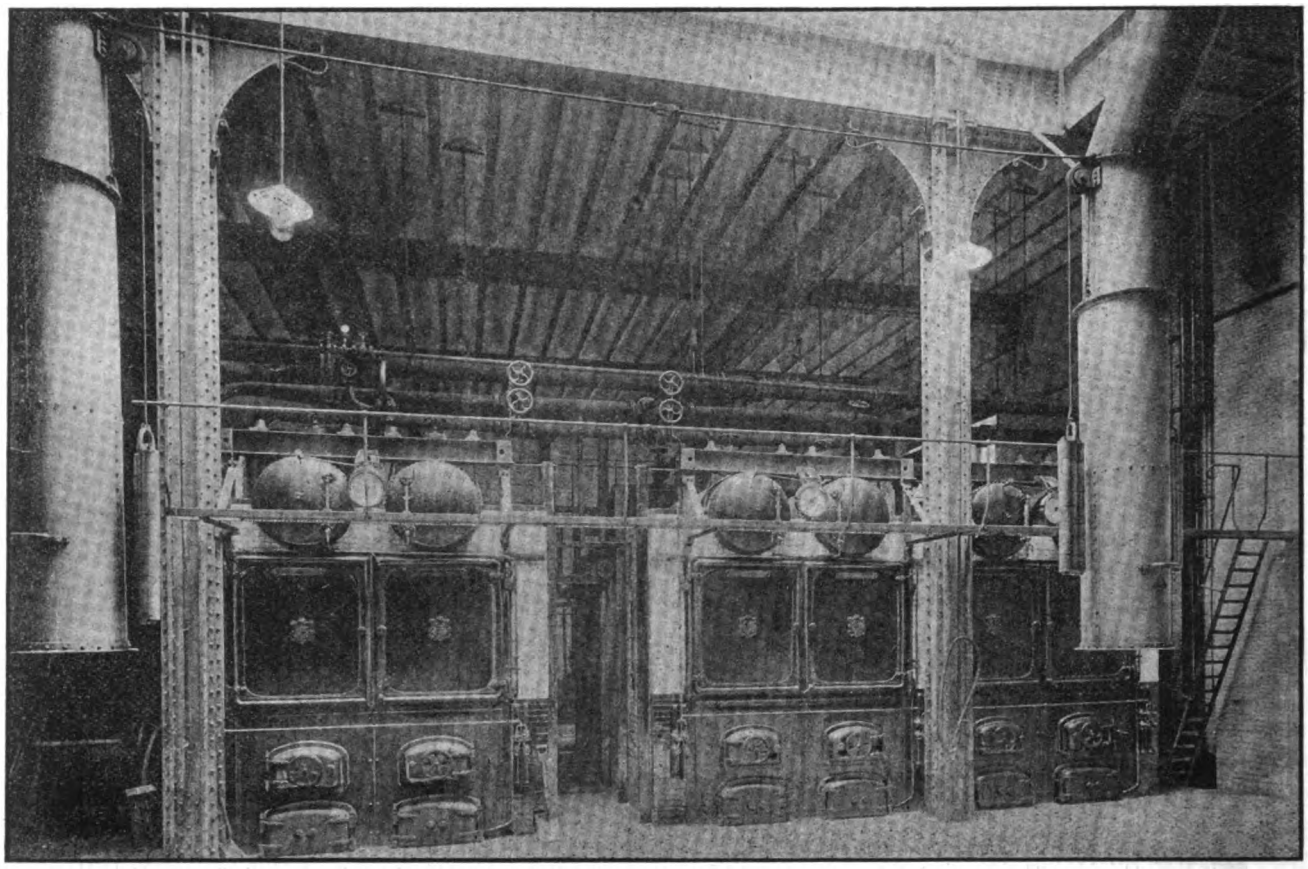
THE STATION BUILDINGS.

The buildings include a boiler and machine room on the ground floor, and on the first floor a battery-room, repairing shop, and stores over the machine-room, whilst the coal-store, water purifiers and tanks are placed over the boiler-room. The chimney, which is 190ft. high and 8ft. 4in. internal diameter at the top, occupies an angle formed by the boiler and machine rooms, and is built of radial bricks and carried on a brick and concrete foundation 15ft. deep. The offices necessary for the administration and the testing-rooms are arranged in the same block of buildings, but occupying a strip of land separating the station proper from the Rue Melsens. The coal-store, which has a capacity of 200 tons, is on the first floor, and an electric lift has been constructed to convey the fuel to it. It is proposed to construct a small tramway to the Willebroeck Canal to facilitate the discharge of fuel brought by water. From the coal-store the fuel is conveyed by suitable shoots to the stoking space—these

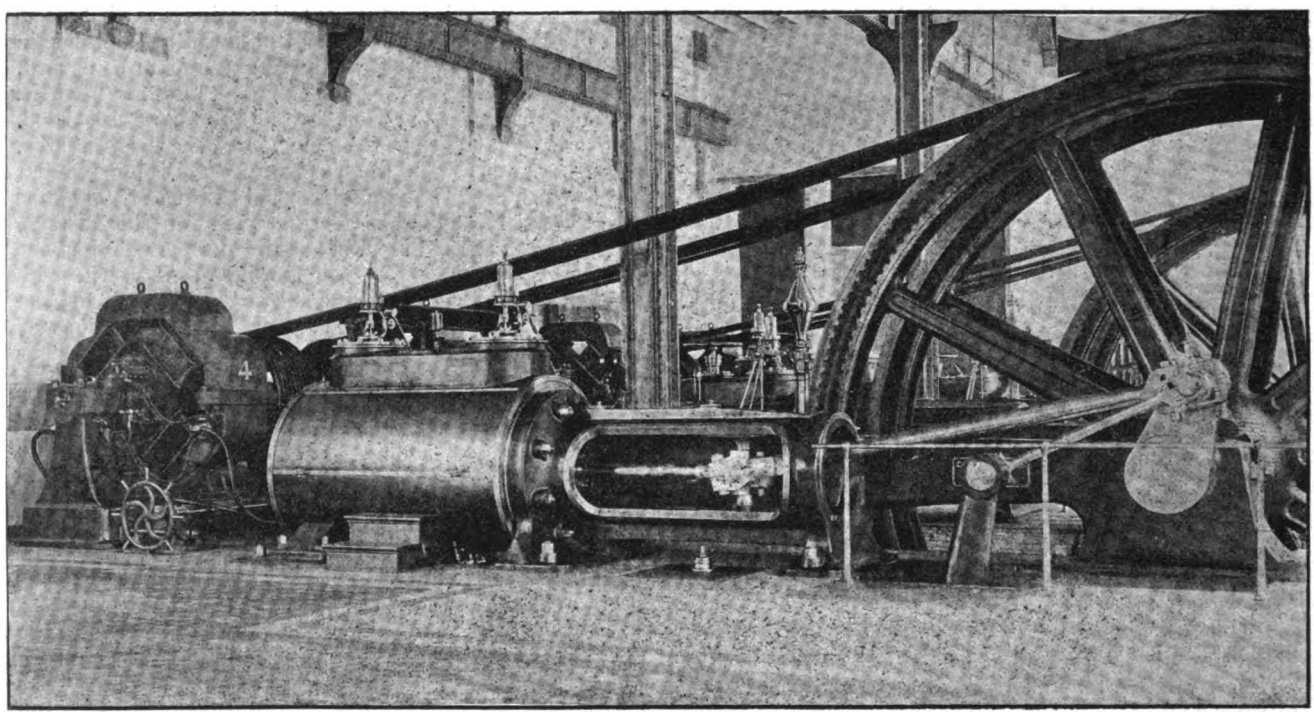
Digitized by Google

shoots being telescopic, so that they may be lowered to avoid the making of dust when coal is being discharged, and raised out of the way at other times. The water supply, both for condensation and feed, is obtained from the Willebroeck Canal, which is distant about 350 yards. Two 18in. pipes have been laid down with a slight fall from the canal to a small reservoir under the machine-room, to which are brought the suction pipes of the condenser pumps. A certain quantity of the condensing water, according to requirements, is pumped up to the water-purifier, from which it is discharged into the main tanks. The water-purifier, which is of the Dervaux type, is capable of dealing with about 2,500 gallons of water per hour, and the capacity of the main tanks—two in number—is about 22,500 gallons.

The station, when complete, will contain plant of 3,000 i.h.p.; the unit adopted being a 500-h.p. engine driving two 250-h.p. dynamos. Provision has been made for laying down six such units, one being a reserve; but as the specification of the municipality stipulated that the machinery should be capable of working at 25 per cent. in excess of its normal full load, the ultimate maximum working capacity of the station may be taken as 3,000 h.p., not including reserve.



Brussels Central Station—The Boiler House.



Brussels Central Station—View of Engines and Dynamos.

Digitized by Google

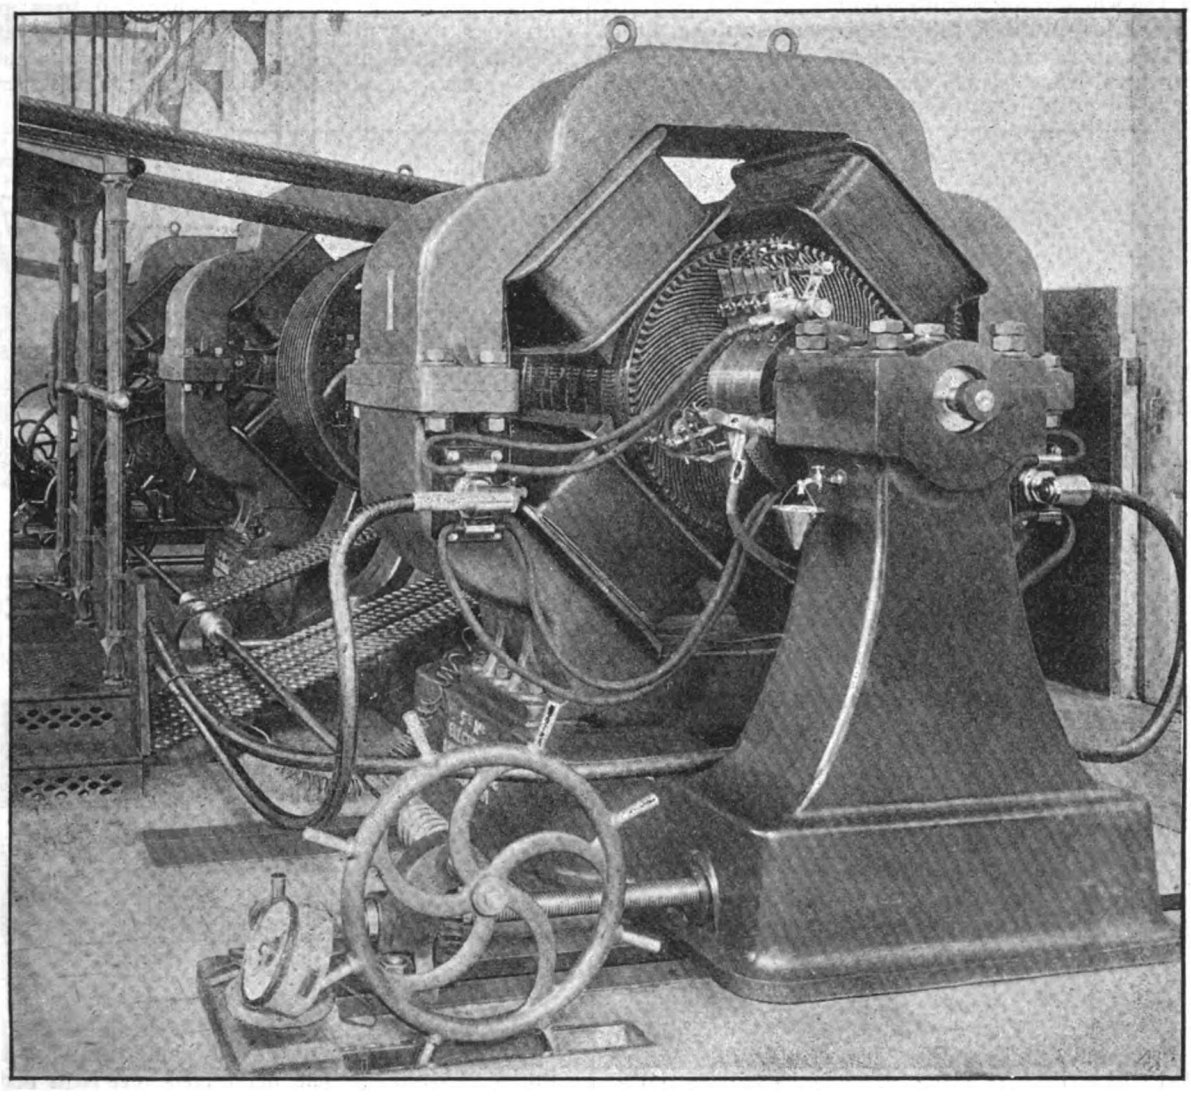
The Boiler-house.

The present plant consists of three Babcock and Wilcox boilers, constructed by Brouhon, of Liège; each has a heating surface of 2,440 square feet, and is capable of evaporating 7,500lb. of water per hour—with a good quality of Belgian coal. The boilers are of the usual type, working at 135lb. pressure, but having a specially large grate surface (56 square feet) to allow of coke being used for firing instead of coal. The boilers are fed by a Worthington pump, a second being held in reserve. Each pump is capable of supplying to the boilers 2,600 gallons of water per hour, the water being drawn from a small cistern at the back of the boilers, to which the water descends from the main tanks, the supply being regulated by a ballcock. This cistern can also be supplied with water from the town mains, in case of an accident preventing the use of the supply from the canal. The feed-water passes from the pumps, through a Green's economiser, of which two have been provided, each of 2,160 square feet heating surface, and thence to the boilers. All the feed piping is doubled, and is so arranged that any boiler can be fed by either pump, the feed-water passing through the economiser, or, in case of repairs to this apparatus, directly to the boiler. All the steam-piping is also double, two main pipes running across the tops of the boilers being carried through into the machine-room, and running in a subway the whole length of it. Each boiler is connected to each of the two main pipes by a branch provided with a stop-valve, and a branch is taken from each main pipe to each engine.

The Engine and Dynamo Room.

The machine-room, which is 120ft. by 52ft. and 28ft. high, contains the engines, dynamos, and switchboard, and is fitted with an overhead traveller running its whole length, and capable of lifting 15 tons. To fulfil the stringent conditions as to the absence of vibration, a block of concrete, about 6ft. thick, has been laid as a foundation, which extends over the whole surface of the engine-room, but it is entirely independent of and isolated from the foundations of the building. On this block the brickwork foundations—also separated from the walls of the building—for the engines and dynamos have been built. The engines, two in number, are of the Sulzer horizontal, side-by-side, compound condensing type, having adjustable cut-off, supplied by Carel Frères, of Ghent.

The low-pressure cylinders are 40in. diameter, and the high-pressure cylinders 26in. in diameter, the length of stroke is 4ft., and the speed is capable of variation between 62 and 75 revolutions per minute, the higher speed being necessary for the charging of the accumulators. Each engine is fitted with two nine-groove fly driving-wheels 20ft. in diameter, and weighing 20 tons. The most economical load for each machine is 400 h.p., so that for a range of 250 h.p. to 625 h.p. the consumption of steam per brake horse-power is small, and a good efficiency should be assured on the average working load throughout the year. For engines of a similar type constructed by the same firm, tests carried out by the association for the supervision of boilers give the following results: On an engine constructed for a normal output of 500 h.p. at 60 revolutions, when working at 138 h.p. with 5·7 atmospheres pressure (85lb.), the steam consumption on a test of eight hours was rather less than 13lb. steam per indicated horse-power hour. With a similar type of engine of 400 h.p. size, working at 5·8 atmospheres (87lb.), and indicating 250 h.p., the steam consumption was 13·1lb. The same engine, tested 5½ years later, gave a consumption of rather less than 14lb., working at 6·9 atmospheres (103½lb.), and indicating 330 h.p.



Brussels Central Station—End View of Line of Dynamos.

Digitized by Google

The engines are erected side by side with the cylinders at right angles to the length of the hall, and each engine drives two dynamos by means of 18 1⅝in. ropes. The dynamos are of the four-pole type, shunt wound, with drum armature, running at 300 to 360 revolutions per minute, with an output of 145 kilowatts as the normal full load, but capable of working up to 180 kilowatts for a continuous run of 12 hours, without over-heating or sparking at the brushes. These dynamos are carried on slide rails, to allow of the tightening of the rope-drive as required, and are fitted with self-oiling bearings. They have been constructed, as was the switchboard, by the Société Electricité et Hydraulique, to designs and plans supplied by the Silvertown Company.

The Dynamo and Switchboard Connections.

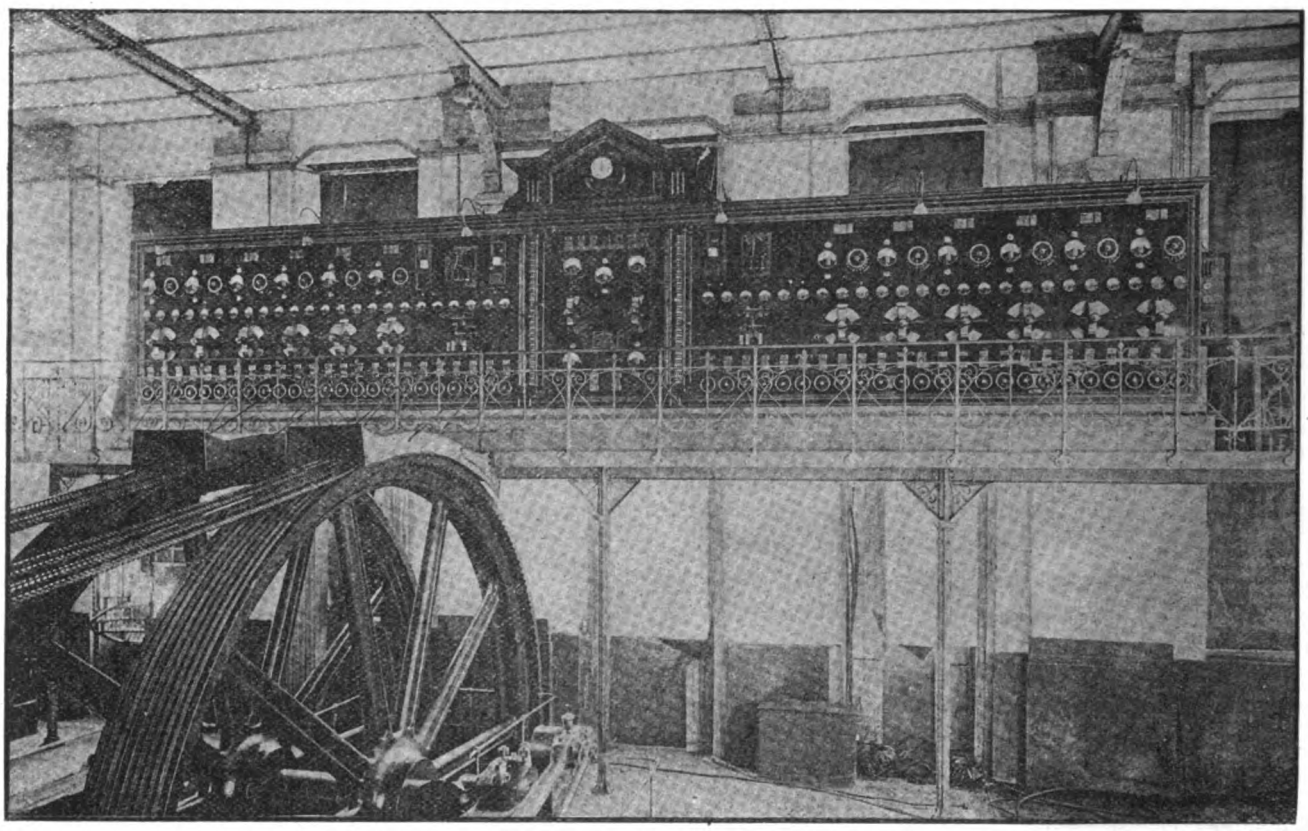
The switchboard is fitted for six pairs of dynamos, a battery of accumulators, and 24 feeders, and is formed of a series of black marble panels carried in a wrought-iron frame, the whole being mounted on a gallery fixed against one of the long walls of the engine-room, at a height of about 14ft. above the floor. Thus the attendants have an uninterrupted view of all the machines. The general scheme of connection of the switchboard is as follows, each set of connections being the same for each pair of dynamos.

The positive pole of No. 1 dynamo is connected permanently to the negative pole of dynamo No. 2, and both are connected through a fusible cut-out to the neutral omnibus bar of the switchboard. The negative pole of No. 1 dynamo is connected through a fusible cut-out and an ampere-meter to the fixed terminal of a two-way switch, by means of which the circuit can be made either on to the charging circuit of the accumulators or on to the negative omnibus bar. The positive pole of No. 2 dynamo is connected in the same way to the accumulators or positive omnibus bar.

The exciting circuit of the dynamo is arranged as follows: the positive terminal of the shunt on dynamo No. 1 and the negative of No. 2 dynamo are permanently connected to the corresponding main dynamo terminals, and therefore to the neutral omnibus bar on the switchboard. The negative terminal of the shunt on dynamo No. 1 is connected to a switch fixed on the dynamo, through which the circuit is connected to the negative omnibus bar, an adjustable resistance fixed on the switchboard being interposed to permit of variation in the exciting current. The positive terminal of No. 2 dynamo is connected in the same way to the positive omnibus bar on the switchboard. The shunt circuit switches on the dynamos are specially arranged to close the circuit of the shunt on that of an auxiliary resistance at the moment of rupture, to diminish the sparking and strains on the insulation caused by the E.M.F. due to self-induction on breaking the circuit.

Distribution.

For the main feeder circuits, of which there are 24, each positive feeder is connected through a separate adjustable main resistance and fusible cut-out with the positive omnibus bar, the negative feeder being connected in the same way to the negative omnibus bar, the intermediate feeder being connected directly to the intermediate omnibus bar. To each distributing centre is led a three-core potential cable, conductor $^{7}/_{20}$ L.S.G., connected at one end to the three main cables in the distributing-box at the centre, and at the other end to a pair of voltmeters mounted on the switchboard, to indicate the pressure between the positive feeder and the intermediate, as also between the negative feeder and the intermediate.



Brussels Central Station—General View of Switchboard.

The pressure is kept constant on each side of the intermediate cable by varying the absorbing resistance in the main feeder circuits. The main resistance is of platinoid strip and fitted with contacts, to allow of separate adjustments of half volt at full load.

The centre panels of the switchboard carry the registering ammeters, automatic switches, battery regulators, etc., for connecting up the accumulators. Twenty-six cells at the positive end of the battery, and the same number at the negative end, are connected to regulator switches; and the middle terminal of the battery is connected to the neutral omnibus bar, thus allowing of the number of accumulators in use to be varied as required. The discharge side of each regulator is connected through a registering ammeter, a switch and fusible cut-out to the corresponding omnibus bar, and the charge side of each regulator through a registering ammeter and automatic switch to the battery contact of the two-way dynamo switches.

The accumulators are of the Julien type, and comprise 140 cells, forming a double battery of 70 cells. Each cell is capable of giving a normal discharge of 350 amperes

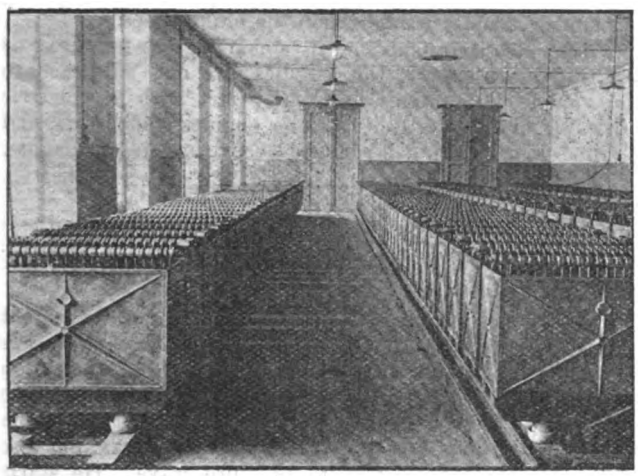
Digitized by Google

for 10 hours, and in case of necessity the discharge may for a short time be carried up to 1,400 amperes without undue deterioration. The cases are of an alloy of lead and antimony. The plates are widely separated, and ample space is left at the bottom for all material that may become detached during work. The total weight of the battery is 80 tons.

The Mains.

For the three-wire distribution, each cable is drawn into a separate cast-iron pipe, with the exception of the potential cable, which is drawn into the same pipe as the intermediate cable. All the cables are continuously insulated, the joints being vulcanised. The conductors are of high conductivity copper—100 per cent. Matthiessen's standard—tinned and insulated pure, then vulcanising indiarubber, taped over all, and the whole vulcanised together, strongly braided flax, and covered with preservative compound. The insulation resistance is 1,500 megohms per mile, tested in water at 60deg. F. after 24 hours' immersion and one minute's electrification.

The whole plant was completed and in working order by October 11, or two days before the date fixed by the contract. The speed at which the work was executed may be further estimated from the fact that, although the definite plan for the system of mains and their laying was only approved by the middle of June, more than 55 miles of pipe were laid, and 26 miles of cable, including a large quantity of 1in. and



Brussels Central Station.—The Battery Room.

1¼in. section conductor, was manufactured in England, delivered, and laid before the opening of the station. The work of canalisation was carried out by Mr. Daubeny, assistant engineer to Mr. Russell. The plant and canalisation have been examined and approved by the experts appointed for that purpose. The station was formally inaugurated by the Bourgmestre and Echevins of Brussels on November 9, since which time it has been giving a continuous night and day service to the complete satisfaction of the town.

Notwithstanding the rapidity with which the work was carried out, the solid construction of the buildings, and the simple but complete establishment of the station, show that durability and efficiency are in no way sacrificed to speed in completion, and at the lunch following the inauguration the India Rubber Company received the hearty congratulations of its guests on the success of the undertaking, and the skill and energy displayed by the company's representatives—Messrs. Gray, Boty, and Russell. It is to be hoped that this, the first central station erected by an English firm in Belgium, may be shortly followed by others with equal success.

The Use of Indiarubber-Insulated Cables.

It is interesting to note that this is the first large central station worked on the low-tension system in which the method of distribution has been carried out with india-rubber-insulated cables. It has hitherto been held that the price of such cables was prohibitory—at least for the larger sizes. This question of prime cost is too often considered at the expense of efficiency, and it certainly appears reasonable that any town having facilities for the borrowing of money at a low rate of interest should not decide only on prime cost, but consider closely the important point of cost of maintenance, since in many cases, if this cost were capitalised, it would be found more economical to incur a heavier initial cost than to adopt any special system merely on account of low prime cost. Although, as we have said, this is the first large low-tension station that has adopted such cables throughout, yet we are glad to see that the company who have carried out the work have in the last year supplied some considerable quantities of these cables to towns where a low-tension system has been adopted—for instance, at Manchester, Glasgow, Dundee, and Paris (where this type is now being largely adopted). For the high-tension system, where hitherto it has been considered that insulation is of more importance than for low tension, we understand this company has supplied, in whole or in part, the cables for the following towns, where the results obtained have been invariably satisfactory: London (over 300 miles in use), Paris, Madrid, Brussels, Dublin, Newcastle-on-Tyne, Leeds, Huddersfield, Blackpool, Eastbourne, Hastings, Brighton, Bournemouth, Scarborough, Chelmsford, Burton-on-Trent, Cardiff, Oxford, Cambridge, Woking, Melbourne, Buenos Ayres, Hong-Kong, Tours, Barcelona, Havre, Rouen, and Montpellier.

Initial Cost is not the First Consideration.

These results go far to prove the fallacy of the idea advanced in the earlier days of electric lighting, when it was held by many electrical engineers that no insulation would be found to be durable underground when employed for high-tension alternating current. The reason of the repeated failures was no doubt the too close consideration of prime cost without regard to maintenance; and it remains now to be proved whether the same considerations do not apply to low-tension distributions, and whether the experiments, extending over a number of years, which were carried out by the electricians interested in telegraphy are to be still ignored, on the supposition that the application of electric lighting is on a totally different footing in all respects from underground telegraphy, and that new insulators have now been rediscovered which can adequately replace the lasting, but no doubt costly, vulcanised indiarubber. A sign of the times is that many of the leading cable-manufacturing companies have within the last few years turned their special attention to the manufacture of this type of cable, and if by so doing these cables can be further cheapened without detriment to their efficiency and durability, a great advance will have been made towards the wider adoption of a reliable insulator.

HOW SHALL WE OPERATE AN ELECTRIC RAILWAY EXTENDING ONE HUNDRED MILES FROM THE POWER STATION? *

In a paper presented at the last meeting of the American Institute of Electrical Engineers, Mr. H. Ward Leonard considered the question of operating an electric railway 100 miles from the power station. The assumption was made that there exists a very economical source of power, possibly a water power, so situated that the length of railway to be operated in either direction is 100 miles.

The following features seem desirable, if not essential, in such a railway: (1) a single trolley contact shall be used for supplying current to the locomotive; (2) the E.M.F. upon the trolley shall not exceed 500 volts; (3) there shall be no apparatus in motion and requiring attention between the power station and the locomotive; (4) no commutator, rheostat, or controlling device on the locomotive shall be subjected to a higher E.M.F. than 250 volts, and there shall be no sparking on any of the apparatus under any normal conditions; (5) the entire control of the locomotive in either direction shall be effected by the movement of one lever; (6) the load shall be started from dead rest by an amount of energy taken from the source of supply which shall not exceed one-quarter of the energy required to

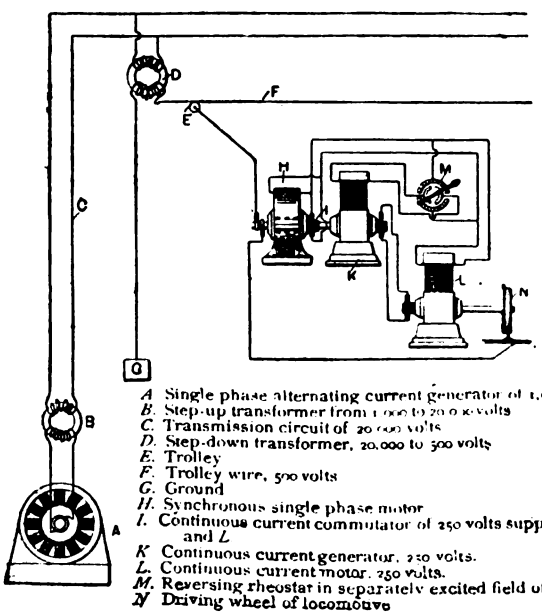
* From the *Electrical World*.

Digitized by Google

operate at full speed on the level; (7) the retardation of the load in coming down grades, and in stopping, shall be effected by converting the motors into generators, which shall feed back current to the line, and thereby assist the power station in operating other locomotives; (8) the motors must be reversible when operating at full speed without damage to the motors or other apparatus; (9) the efficiency of the system from power on the generator shaft to the drawbar pull of the locomotive shall be at least 50 per cent.; (10) the locomotive shall produce at least 500 h.p. when operating at a speed of 80 miles per hour.

For such great distances, in order to operate with a loss in conductors of 20 per cent., the initial E.M.F. must be 20,000 volts, in order to make the cost of copper 20dol. per kilowatt, which is about the best figure for cost of copper under the conditions. The alternating current must evidently be used, and as there is but one trolley contact, it must be single phased.

The system proposed, which is diagrammatically shown in the accompanying illustration, is briefly as follows: Starting with standard 1,000-volt, single-phased alternators in the power station, the potential is raised to 20,000 volts by step-up transformers. At suitable points, say every two miles, the potential is transformed down to 500 volts. Now, with this current, a synchronous alternating motor can be operated, but cannot be regulated in speed, reversed,



A. Single phase alternating current generator of 1,000 volts
B. Step-up transformer from 1,000 to 20,000 volts
C. Transmission circuit of 20,000 volts
D. Step-down transformer, 20,000 to 500 volts
E. Trolley
F. Trolley wire, 500 volts
G. Ground
H. Synchronous single phase motor
I. Continuous current commutator of 250 volts supplying fields of *H*, *K* and *L*
K. Continuous current generator, 250 volts.
L. Continuous current motor, 250 volts.
M. Reversing rheostat in separately excited field of *K*
N. Driving wheel of locomotive

Operation of Long Distance Railways.

or started under load. It is evident that some form of gearing between the synchronous motor and the axle will solve the problem. Let the synchronous motor drive a direct-current generator and use the current thus generated to supply the motors connected with the axles of the locomotives. This portion of the system is the same as the well-known Leonard system, as applied to elevators. Regulation is secured by varying the field of the generator supplying the motors, and by weakening, strengthening, or reversing the field of this machine any desired speed or direction can be obtained. The continuous-current generator should have its field separately excited. The propelling motors can be series, shunt, or separately excited, but the best results will be obtained by separate excitation. To secure exciting current for the alternating motor and the fields of the continuous-current generator and motor, it will be best to drive by means of the alternating-motor armature, and if desired in the same field, a continuous-current winding connected to a commutator, from which will be led the current for exciting the fields of all three machines. The fields should be wound for 250 volts, and this same voltage used for the continuous-current armatures.

Suppose now the locomotive to be at rest. The synchronous motor is running and driving the generator armature at full speed in a field of no intensity; hence the propelling motors receive no current. The first contact upon the rheostat in the generator field circuit is now made, and let the resistance in the rheostat be such as to produce, say, 25 volts at the generator brushes. This 25 volts will supply a very large current to the motor armature at rest in its saturated field, and consequently will produce a sufficient torque to start the entire load and continue to move it at a slow spoed. There is now being used 25 volts and, say, 2,500 amperes in this circuit; this means 62,500 watts, and disregarding transformation losses for simplicity, this means a current of 125 amperes from the trolley. When operating at the rate of 500 h.p. at full speed there will be needed, say, 1,800 amperes and 250 volts in our propelling circuit, which is 450 kilowatts, and means, roughly, 900 amperes from the trolley. It is evident, therefore, that the load can be started with but a small fraction of the energy required for operation at full speed, and that there will be no danger of throwing the alternator out of step by applying but one-sixth of its full load.

If operating at full speed, and it is desired to bring the locomotive to rest, the strength of the generator field is rapidly reduced by manipulating the rheostat in its field circuit so as to reduce to zero the current exciting this field; the E.M.F. produced by the generator then rapidly falls below the counter E.M.F. of the motors, which are being driven in a constant field by the momentum of the moving load, and the motors consequently become generators and supply current to the former generator, which now becomes a motor, and driving the alternator, feeds current back through the trolley, thereby not only bringing the locomotive smoothly and rapidly to rest but saving the energy usually wasted upon the brake shoes.

Under this arrangement, if steam-engines are used as the source of power, the engines are not subjected to the violent fluctuations ordinarily met with in electric railways, and the capacity of the engines, generators, and conductors can be much reduced over usual requirements.

VOLTMETERS IN ALTERNATE-CURRENT STATIONS.

The subject of using voltmeters in alternate-current stations is treated by Mr. B. Szapiro in the *Elektrotechnische Zeitschrift*. The author remarks on a small correction necessary in voltmeters containing iron when used with alternating currents. He points out that the reading of the voltmeter depends, not merely on the frequency, but also on the shape of the alternate pressure wave. He starts with the general equation:

$$E^1 = E_1 \sin mt + E_3 \sin (3mt + \alpha) + E_5 \sin (5mt + \beta) + \ldots,$$

representing any curve which is symmetrical as regards the axis of abscissæ, and works out values for the effective current; from which he draws the general conclusion that in a certain circuit of given resistance and self-induction the strength of current for a given effective pressure varies with the shape of the pressure curve. In particular, where the self-induction is relatively small the strength of current is independent of the pressure curve; when the curve is nearly a sine function, and the resistance of the circuit comparatively large, no very great difference occurs in the value of current with different E.M.F. curves. But if the resistance and self-induction are of the same order of magnitude, the differences in current-strength may be very noticeable. And in taking the particular case of a Ganz machine the author finds for a voltmeter of resistance 1,000 and coefficient of self-induction = 1 that the error is about 8 per cent. The author therefore advises that all iron instruments should be calibrated on the alternator for use with which they are designed.

Electrical Conductivity of Cupric Chloride Solutions.—Mr. R. J. Holland, in the *Ann. Phys. Chem.*, states that solutions of cupric chloride show a regularly diminishing rate of increase of the conductivity as the temperature rises, and then varies with the concentration, the maximum conductivity being obtained with a solution containing about 18 per cent. of anhydrous salt. The temperature coefficient varies with the concentration, and reaches a maximum at about 40deg.

ELECTRIC LIGHT PROVISIONAL ORDERS AND TRAMWAY ORDERS AND BILLS.

BOARD OF TRADE REPORT FOR SESSION 1894.

The report by the Board of Trade upon all railway, tramway, gas, and water Bills and provisional orders for the 1894 session has just been issued. We give the following concerning the applications for electric lighting provisional orders and for tramway provisional orders and Bills. Of the former there are 26 applications and of the latter, 13:

ELECTRIC LIGHTING PROVISIONAL ORDERS.

Aberdare Electric Lighting Order.	To authorise J. C. Howell, Limited, to supply electricity within a portion of the district of the Aberdare Local Board.
Barrow-in-Furness Corporation Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Barrow-in-Furness to supply electricity within that borough.
Bedford Electric Lighting Order.	To authorise the Bedford Electric Light Company, Limited, to supply electricity within the municipal borough of Bedford.
Birmingham Electric Light and Power Order.	To authorise the Birmingham Electric Supply Company, Limited, to supply electricity within certain portions of the city of Birmingham.
Buxton Electric Lighting Order.	To authorise the Buxton Local Board to supply electricity within the urban sanitary district of Buxton.
Chelmsford Electric Lighting Order.	To authorise Crompton and Company, Limited, to supply electricity within the borough of Chelmsford.
Chepping Wycombe Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Chepping Wycombe to supply electricity within that borough.
Chesterfield (Corporation) Electric Lighting Order	To authorise the mayor, aldermen, and burgesses of the borough of Chesterfield to supply electricity within that borough.
Clonmel Corporation Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Clonmel to supply electricity within that borough and certain portions of the district of the Clonmel Union.
Collier-Marr Moss Side Electric Lighting Order.	To authorise the Collier-Marr Telephone and Electrical Manufacturing Company, Limited, to supply electricity within the urban sanitary district of Moss Side.
Crystal Palace District Electric Lighting Order.	To authorise the Crystal Palace District Electric Supply Company, Limited, to supply electricity within portions of the district of the Beckenham Local Board, the borough of Croydon, the parish of Lambeth, the district of the Lewisham District Board of Works, and the parish of St. Giles's, Camberwell.
Grimsby (Corporation) Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Grimsby to supply electricity within that borough.
Guildford Electric Lighting Order.	To authorise the Holloway Electricity Supply Company, Limited, to supply electricity within the borough of Guildford.
Harrow Electric Lighting Order.	To authorise the Harrow Local Board to supply electricity within the urban sanitary district of Harrow.
Leyton Local Board Electric Lighting Order.	To authorise the Leyton Local Board to supply electricity within their district.
Monmouth Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Monmouth to supply electricity within that borough.
Oswestry Electric Lighting Order.	To authorise the Oswestry Electric Lighting and Power Company, Limited, to supply electricity within the borough of Oswestry.
Peterborough Electric Lighting Order.	To authorise the mayor, aldermen, citizens, and burgesses of the city and borough of Peterborough to supply electricity within that city and borough.
Plymouth Corporation Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of Plymouth to supply electricity within that borough.
St. Austell Electric Lighting Order.	To authorise Veale and Co., Limited, to supply electricity within the district of the St. Austell Local Board.
St. Helens Corporation Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of St. Helens to supply electricity within that borough.
Shropshire Electric Lighting Order.	To authorise the Shropshire Electric Light and Power Company, Limited, to supply electricity within a portion of the borough of Shrewsbury.
Stirling Electric Lighting Order.	To authorise the Caledonian Electric Supply Company, Limited, to supply electricity within the Royal burgh of Stirling.
Wakefield Corporation Electric Lighting Order.	To authorise the mayor, aldermen, and citizens of the city of Wakefield to supply electricity within that city.
West Hartlepool Electric Lighting Order.	To authorise the mayor, aldermen, and burgesses of the borough of West Hartlepool to supply electricity within that borough.
Yeadon Electric Lighting Order.	To authorise the Yeadon Local Board to supply electricity within their district.

TRAMWAY PROVISIONAL ORDERS.

Barrow-in-Furness Corporation.	To authorise the construction of additional tramways in the borough, on a gauge of 4ft., to be worked by animal, mechanical, or electric power; and to enable the Corporation to work the tramways in certain circumstances.
Croydon Corporation....	To authorise the construction of tramways in the county borough, to be worked by animal power, or, with the consent of the Board of Trade, by electrical, steam, or any mechanical power; and to empower the Corporation to borrow £2,500, and such further sums as the Board of Trade might sanction.
Croydon (extensions)....	To authorise the construction of tramways in Croydon and Streatham, on a gauge of 4ft. 8½in., to be worked by animal power, or, with the consent of the Board of Trade, by electrical, cable, mechanical, or other power; the erection of posts, wires, etc.; the removal of certain existing tramways; the raising of £40,000 additional share capital, and borrowing of £10,000.
Dudley and Wolverhampton.	To authorise the construction of tramways in Dudley, Wolverhampton, and Bilston, on a gauge of 4ft. 8½in., to be worked by animal power, or, with the consent of the Board of Trade, by steam, cable, electrical, or other traction.
Liverpool, Bootle, and Walton-on-the-Hill.	To authorise the construction of tramways in Bootle and Walton, to be worked by animal or mechanical power
Liverpool Corporation..	To authorise the construction of additional tramways in the city of Liverpool, to be worked by animal, steam, electrical, or any mechanical power; providing for lease to Liverpool United Tramways and Omnibus Company; and for borrowing £5,100.
South Staffordshire.....	To authorise the construction of tramways in West Bromwich and Handsworth, on a gauge of 3ft. 6in., to be worked by animal power, or, with the consent of the Board of Trade, by cable, electrical, mechanical, or other power; and the removal of existing tramways for which proposed tramways are to be substituted.
West and East Hull ...	To authorise the construction of tramways in Hull, on a gauge of 4ft. 8½in., to be worked by animal or mechanical power; and enabling the Corporation of Hull to purchase the tramways.

TRAMWAY BILLS.

Aberdeen District	To authorise additional tramways, including a doubling of existing single lines and certain lines already laid by consent of local authority
Bristol	To authorise additional tramways, being mainly a doubling of existing single lines, to be worked by animal, electrical, or mechanical power.
Harrow and Paddington	To further extend the time for the compulsory purchase of lands and for the completion of the tramways authorised by the Harrow-road and Paddington Tramways Act, 1891.
London Tramways Company, Limited.	To authorise extension tramways, to be worked, with the consent of the Board of Trade, by cable power.
West London.	To incorporate the West London Tramways Company, and to authorise tramways in Acton, Hammersmith, and Fulham, to be worked by electrical or mechanical power other than locomotive steam power; and providing for running powers, and purchase of, West Metropolitan tramways.

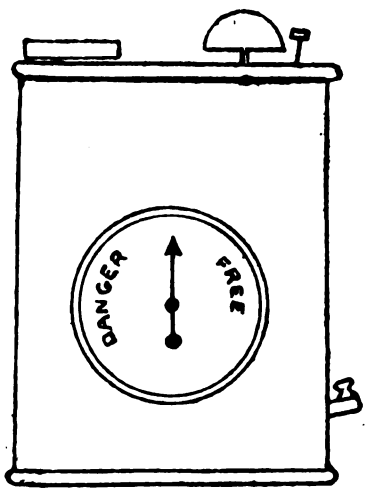
TRADE NOTES AND NOVELTIES.

AN ELECTRIC FOG SIGNAL.

The annual invasion of the fog and smoke fiend means, as we all know, an enormous outlay by the railroad companies upon torpedoes or audible explosive fog signals; and this outlay is almost inversely proportional to the satisfaction and efficiency given by such a method of notifying to engine-drivers the position of semaphore arms which they cannot possibly see. Consequently, there have been endless endeavours made by the railway telegraph engineers, as well as by outsiders, to effect some radical improvement in the methods still used quite generally throughout the country; but the fact that none of these efforts are to be seen in actual extensive working shows clearly that, however excellent may be their theoretical basis, they have no real practical worth.

The one great defect in all these appliances—assuming that they are reliable and automatic in action—lies in the fact that they still offer the same opportunities for mutual mistakes and errors on the part of signalman and driver, as in the case of clear weather and ordinary signals—that is, either the signalman or driver may unwittingly commit an error although firmly believing the contrary, and hence the contradictions almost invariably arising after an accident. Railway men are, as a rule, of a sufficiently respectable class to ensure acting up to their best judgment, and hence the question of wilful misunderstanding may in nine cases out of ten be put aside.

It is, however, most important to nail down an error to the signalman or driver as the case may be, and the apparatus herein noticed has this object in view. Brief descriptions have



already appeared in some of the technical papers, owing to some trials recently held on the Tottenham and Forest Gate Railway—now under construction—but it is difficult to fully appreciate the contrivance without illustrations. We therefore append a small diagrammatic section and elevation of the appliance used with this system, and fixed on the locomotive in order to warn the engine-driver as to the position of signals.

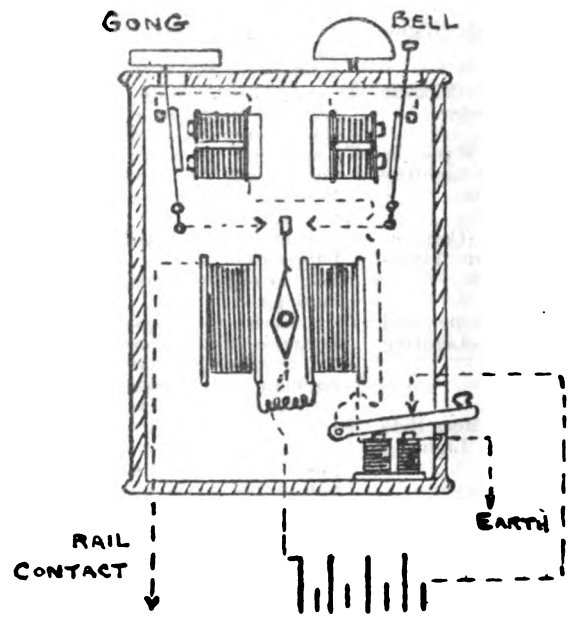
The whole method is the joint invention of Messrs. I. A. Timmis and G. N. Abernethy, and consists essentially of two signal repeaters—one in the cabin and one on the locomotive—in series one with the other, so that any indication on the one is also shown on the second.

Each signal-post is provided with a small primary battery—say, three Leclanché cells—and the signal-arm works a double-pole switch, which sends a current from the battery along a single wire to a repeater in the signal cabin. The double-pole switch determines—by the position of signal-arm—which pole of the battery the current comes from. The circuit goes through the repeater in the cabin, and back along another wire to a long contact-piece placed alongside one of the rails on a block of wood or similar insulating material. So far there is no complete circuit, and the repeater in the cabin does not work; but when the locomotive approaches the signal a contact brush, fixed to the engine frame, travels along the insulated contact-piece already alluded to, and completes the circuit through another repeater on the locomotive, and on through the frame and wheels to earth. It will thus be seen that the repeater in the signal-cabin and that on the locomotive are in series with each other and the signalman is able to act as a check on the engine-driver.

The repeat signal on the locomotive consists of an indicating needle or arm on a dial, and also two bells of different tone, or a gong and a bell; whilst in order to show afterwards what signals have been received on the engine, there is provided an appliance for recording these in connection with the indicator. Similar arrangements are used for the cabin repeat signal, though the bells are not in this case absolutely necessary. Small electric lamps—red and green—might, for instance, be switched in.

The ordinary permanent signal repeaters, such as are usually to be found in signal-cabins, are worked by the same line wire as that which operates the fog repeaters, the two sets being thus in parallel. The advantages claimed for this system are therefore the following: first, the driver knows the position of each signal-arm as he comes up to it, both visually and audibly; second, the signalman is kept equally well informed as to whether each signal is at "danger" or "line clear"; third, he also knows when a train passes a signal; and last, but not least important, a record is kept, according to which the blame for neglect or carelessness may be properly assigned.

Referring to the illustration, it will be seen that when the engine passes over the rail contact a circuit is completed through the large central coils, thereby throwing the dial arm or needle to right or left according to the direction of the current from signal-post battery. This current, it will be remembered, may be sent through the circuit either way by the double-pole switch attached to and operated by the semaphore arm, the dial needle being deflected accordingly. If, for instance, the needle swings over to the left, it makes contact by means of an extension piece above, with one of two contacts also acting as stops. This sends a current from a small battery, carried on the engine, through the magnet coils in the upper left-hand corner, thereby ringing the gong. Similarly, a deflection of the needle to the right sends the local current through the magnet coils at the top right-hand, so as to ring the bell.



In the lower right-hand corner of the apparatus are seen two small magnet coils, with a key lever above them pressing against a contact, through which the local circuit must be completed. In case the engine should come to rest anywhere on the insulated line contact-piece, the driver is able, by depressing the key, to break the local circuit, and thus prevent the gong or bell from ringing uselessly after once giving warning as to the position of signal.

GAS EXPLOSIONS IN ELECTRIC LIGHT CULVERTS.

A report has been made by Prof. Kennedy on the subject of the explosions which occurred in certain junction-boxes in Glasgow towards the end of last year. The professor, who paid a two days' visit to the city and investigated four explosions, concludes that they were due to the accumulation of the gas in the service boxes, the accumulation being such as to eventually form an explosive mixture. Reporting on the explosions, Prof. Kennedy says:

"I cannot doubt that in the case of the explosions on November 9 and 10 the ignitions were actually caused by electrical action. The existence of serious electrical leakage had been shown by the tests at the station for two or three days before the accident, but the position of the leak had not been determined. I feel sure that if any such leakage were to show itself again it would be now possible for your staff to localise it and remove it in a few hours instead of allowing it to go from bad to worse for several days. The primary cause of the accident of November 9 was a piece of exceeding careless work in connection with the main-laying, which had unfortunately passed without detection. The more serious trouble of November 10 was due to a potential lead, the copper in the troughs being dead at the time. The several explosions which occurred during the work of main-laying, and also that on December 29, were, of course, due to the simple ignition of an explosive mixture by a naked light. The cause of the explosion on December 26 is not at all clear. There is absolutely no evidence that it was electrical, and the conditions are such as to render an electrical ignition so extremely improbable that I think the explanation of a chance ignition by a match thrown down—although not at all satisfac-

Digitized by Google

tory—is, on the whole, a less likely one. I am sorry that the result of my investigation as to this matter is so entirely negative. The accidents which have occurred, with the possible exception of the first one in Mains-street, have been in no way connected with the use of troughs or of pipes. It has always been the accumulation of gas in the service boxes which has been the cause of explosion. Even under ordinary circumstances it is, of course, impossible to prevent some leakage of gas from gas-mains. Under the existing condition of the Glasgow streets, however, in connection with the various underground works which have been going on, all difficulties of this kind are increased tenfold. Under these circumstances it is undoubtedly necessary that the greatest watchfulness should be shown as to the state of the boxes, especially those near which leakage of gas is known to exist. I have no doubt that the gas department is ready to take advantage of all indications of leaks shown by smell in the service boxes, and to localise and remove them as rapidly as possible."

The following precautions are recommended in the hope that they will so minimise the risk of explosion from the ignition of gas leaks that the authorities need not have further anxiety on this account :

"The covers of all boxes in which any gas leak has been found or is suspected, and also the covers of all boxes towards which gas would naturally ascend if it leaked into the pipes or troughs, should be periodically lifted and the boxes carefully examined. The examination would be best made with a little hand battery lamp, from which there could be no possible risk of ignition. It would be advisable also to use a gas detector in these examinations, as this appears to be more certain in its indication than the sense of smell alone. All boxes should be kept clean and dry. There had been a very great leakage of mud and dirt into several which I examined. I cannot say—but an examination would at once show—whether this mud came down through the joint between the cover and its frame, through the joint underneath the frame, or actually through the walls. I think, however, most of it came down from the top. This can be easily remedied by a more complete jointing of the covers in their frames—this is, I am sure, essential, in spite of the additional trouble it entails every time the cover is lifted—by making quite certain that there is a good joint below the frame on the top of the brickwork, and, if necessary, in any special cases, by cementing the whole of the brickwork on the inside. I attach very great importance to the state in which the boxes are kept, for I think this is very much more than a mere matter of tidiness. Unless the boxes are well kept, one can never be sure that they are properly examined, as the men will always shirk going down into them. Moreover, any joint below the surface which could let mud or water enter would also allow of the easy entrance of gas. If there are any signs in particular boxes that the gas rises up through the floor, the bottom should be treated as a number were treated during the construction of the mains—*i.e.*, it should be covered with cement concrete and drained through a trap to the nearest sewer. Various plans have been proposed for ventilating the boxes and mains generally. To ventilate them by connecting them to a chimney—*i.e.*, by reducing the air pressure all over them—would be, I think, a mistake, for it would necessarily be the means of drawing in gas, and not of keeping it out. To ventilate them by keeping a flenum in them by means of a fan (supposing that this could be done) would, of course, prevent gas from getting in ; but it would have the somewhat serious drawback that it would be liable to send any gas that did get in, or any foul air of any kind, into the houses, through the service pipes. It could hardly be supposed that these would universally be so plugged up, and would remain so plugged up, that nothing could pass through them. I think that probably there would not be any really serious risk from this, but I feel sure that it would be very much disliked by your consumers, and that there would be many complaints about it whether their causes would be real or fancied. The most practicable method of ventilation appears to me to be the ventilation of individual boxes by pipes carried up the side of adjacent buildings. I have also reason to believe, unofficially, that this method would meet with the approval of the advisers of the Board of Trade. I think, therefore, it is desirable that you should adopt it in connection with some of the boxes in the centre of the city where the gas leakage into the soil is largest, and also at other places where there are boxes at the top of inclines, or any places where, for any reason, gas may or may be likely to accumulate. Of course, I am aware that such ventilating-pipes cannot be carried up the sides of buildings without permission, but I hardly suppose that there can be any practical difficulty in getting such permission in a reasonable number of places. The suggestion has been made by one of the authorities in London that each suspected box should be connected by a short pipe to a small cast-iron box, open through a grating (in the pavement) to the atmosphere. This little box would be itself connected to a neighbouring gully or drain to carry off the water and mud which would fall into it. There is obviously no difficulty in carrying out this suggestion, which I mention because of its apparent reasonableness. If, however, from any cause the plan failed at any time to keep the box free from gas accumulations—as I fear it might fail—it would then become an obvious source of danger from chance ignitions on the pavement. A suggested modification of this plan—the use of two separate grating boxes on opposite sides of the brick box, in order to ensure a through draught—is an improvement, and would certainly be very much safer, although more costly. I think it might properly be adopted in cases where the permission to ventilate as I have above suggested could not be obtained."

THE COMMERCIAL PROGRESS OF ELECTRICITY.

A letter on this subject has been addressed to the *Times* by Major S. Flood Page. The letter is as follows :

Those who are connected with electrical trade are constantly being asked by those whom they meet in society, or when travelling, or in the course of general business, whether there is any real commercial progress in the electrical industry. That we have made decided and considerable advance is well known in the trade itself, most of us being very busy, and is not a matter of doubt to those who read the technical journals ; but as the public generally have not access to our admirably-written and well-conducted electrical weeklies, and as we are constantly challenged as to the progress we are making in the most modern application of science to industry, perhaps you will grant me a little space in your columns in which to report progress.

Let us cast one glance backwards as to the date from which electric lighting as we know it really commenced. In August, 1877, a small body of men were invited by Messrs. Dennayrouze and Co., of Paris, of whom only three were Englishmen, to witness an exhibition of the Jablochkoff candle lamp. Never shall I forget our astonishment as this bright, piercing, powerful, and steady arc lamp was lighted up and extinguished. In the spring of 1878, the year of the exhibition in Paris, when our French friends boldly invited Europe to see that they had risen from their recent misfortunes, we all saw the Avenue de l'Opéra brilliantly lighted by the Jablochkoff lamp, which was shortly afterwards in use on the Thames-embankment, though before that, if my memory does not fail me, I was taken to see electric light in use in the offices of the *Times*, one of the very first places in England in which the electric light was in regular and constant use. I think, Sir, the lamp which was in use in the *Times* office was the Rapieff. We may then date the birth of modern electric lighting from the spring of 1878—only 16 years ago. The incandescent lamp was not yet in use. Sir William Thomson (Lord Kelvin), when under examination before a Parliamentary Committee on May 23, 1879, said : "I believe the Jablochkoff candle is the most advanced sub-division of the electric light which we yet have." Mr. Edison's key patent for incandescent lamps was dated November, 1879 ; Mr. Swan's, January, 1880 ; but it was not until 1881 that the manufacture of incandescent lamps became of any importance. A few were made in laboratories, a fair number in experimental factories before that date, but not many were seen in practical use before the Paris Electrical Exhibition in 1881, and in England at the Crystal Palace Exhibition in 1882. So that for practical purposes we may take it that electrical lighting on a commercial scale is not more than 12 years old.

I need not touch on the progress of telegraphs, on which the country has spent several millions of pounds, the expenditure on telegraphs being £2,739,010 for 1893-94, for that, though electrical, is an old story and dates from 1839, or submarine cables dating from 1858.

Neither is it necessary to dwell on the wondrous development of telephones—on which nearly £5,000,000 have been spent by the company and the Government, by which messages have been spoken in the past year to an extent not far, if anything, short of 200,000,000, at, I suppose, an average cost of about a halfpenny, many of the conversations lasting some minutes—except to protest against the muddle which the Government has introduced into telephonic business, to the serious hindrance of business and of progress, and to express the opinion, not for the first time, that the sooner the Government purchase the whole of the telephonic interests the cheaper will be the price to be paid, and the more efficient will the service be made. Nor shall I refer to the great and immediately future question of traction which will greatly suffer unless wisdom is shown and concession of the authorities granted in the regulations which are now being drawn up by the Board of Trade in consultation with the Institution of Electrical Engineers and those concerned with electrical traction ; but I limit myself almost entirely to the progress of the supply of electricity for lighting and for motors, as exemplified in the position of the electric supply companies in the United Kingdom.

At the present time we have some 60 supply companies engendering and supplying electricity, of which 19 are the property of, and worked by, local authorities, 41 by limited companies ; the amount of capital may be taken as about £5,125,000. As much work is in progress and fresh stations are being constantly opened, it is difficult to be exact as to the amount of capital expended ; that which is right to-day will be incorrect in a month.

In addition, 24 local authorities have stations in course of construction, and some 20 companies and local schemes have been sanctioned. These two heads give a further sum as being spent, or about to be spent, of, say, £1,350,000, so that it will not be far wrong to say that the amount expended, or being laid out, or shortly to be spent in electric stations reaches about £6,500,000.

When we come to consider results, we must bear in mind that local authorities do not aim at paying dividends, as when the local authorities own gasworks some strive to sell gas at the lowest remunerative rates. So do they naturally act with the electric stations. Nevertheless, many of the results are fairly satisfactory, and considering the infantine position of local authority supply stations may be considered very hopeful.

Some of the supply companies have not been working long enough to give results yet, and naturally those who can afford the luxury of having their houses fitted for the reception of an electric supply wait to see how their more enterprising neighbours like the light, and how much it costs, before themselves incurring

Digitized by Google

the expense of having their houses wired. So that there are very few companies, and none in their earliest years, who are able to sell the whole of the electricity they can engender for lighting, and so backward are we in the use of motors that very few companies are able to dispose of the electricity which could be engendered during the day and sold at a very cheap rate.

Obtaining my information partly from the electrical journals, and partly from Skinner's Stock Exchange Book, and from reports of various companies, the secretaries of which with courtesy do me the favour, without application on my part, of sending me their reports, I conclude that some 18 companies have paid dividends for the years 1892-93 (some only paying a dividend on preference stock) varying in amount from 2½ to 7½ per cent. That nearly every well-managed supply company will eventually pay dividends I have no reasonable doubt; that any of them should pay any dividend in their early days, and that some should pay a fair dividend, is most hopeful and encouraging.

I can well believe that our gas company friends may say I am easily satisfied, that our dividends are paltry, that we live on hope, and, in the assurance of their own steady dividends, can laugh and pour contempt on our humble efforts. But our progress has been phenomenal when compared with that of gas. On May 13, 1879, Mr. Corbett Woodall, M.I.C.E., engineer-in-chief of the Phœnix Gas Company, gave evidence before the Parliamentary Committee to which I have already referred, and said "As a rule in early years gas companies did not pay any dividend at all, or a very small one. Before coming away I sought to find the dividends paid by my company since 1824. I was unable to find them up to 1851, but I believe they never reached 3 per cent. before 1851." That is for 27 years. Surely we have good ground for hope.

At any rate, we have advanced far beyond Mr. Woodall's expectations, for he went on to say that he had no fear that electric light would compete with gas inside houses, as no system had been heard of by which a company could lay wires and send off branches into separate houses or premises, and that it would be necessary to have telegraphic communication from the user to the producer in order that the light might be turned off when no longer required.

I do not recall this gentleman's evidence with any notion of blaming him that he was unable to see how very nearly the whole problem was to solution, when neither he nor other intelligent scientists and engineers believed it was capable of solution; but as a measure or standard by which the extraordinary and unexpected progress which has been made in electric lighting can be gauged when so eminent a professional man committed himself to such opinions no further back than May 13, 1879—not 15 years ago.

While there is nothing novel in this letter, I trust it may show some of your readers that the progress in electric lighting is steady, is real, and that the industry is worthy of support, and that, where strong foundations are laid, there is good hope, with good management, of a fair and progressive return on money invested in such electric companies.

I cannot occupy your space by reference to the vast amount of work which electricity has found for engineers, engine-makers, boiler-makers, wire-makers, and the manufacturers of electrical fittings, apparatus, and instruments, which is not to be despised in these days of dull trade, as these branches give work to many thousands of people.

In conclusion, permit me to say that it seems as if the problem of electrical locomotion on existing lines of railway, and on tramways, is on the point of solution without any alteration of the present lines of railway and of tramways, by means of a great step in advance which has been made by a couple of able French practical engineers, and if my expectations in this respect are not too sanguine—and I have some confidence in their soundness—this advance must also have a very great effect on the progress of electric lighting.

The electrical success of the South London Railway and of the Liverpool Overhead Railway are as gratifying as indisputable.

COMPANIES' MEETINGS.

HOUSE-TO-HOUSE ELECTRIC LIGHT SUPPLY COMPANY, LIMITED.

The sixth ordinary general meeting of this Company was held at the central station, Richmond-road, Earl's Court, on the 22nd inst. Mr. Henry Ramié Beeton, the chairman of the Company, presided.

The **Chairman**, in moving the adoption of the report and accounts, which were given in our last issue, stated that the history of the year could be shortly told. There had been a steady growth of business, and there was a greater rate of progress during 1893 than during 1892, though not to the same extent as in 1891. The Company had been affected by the general depression in trade, as possible consumers had postponed adopting the electric light. The income per lamp had fallen off, the causes being partly temporary and possibly partly general. The temporary cause was to be found in the absence of fog, and a permanent cause was to be found in the fact that consumers were becoming very clever in economising, and it was therefore natural that the income per lamp should be less. There was, however, a satisfactory feature in the accounts, that the Company had earned an increased income at a decreased expenditure. This gratifying point was mainly due to the efforts of Mr. William Page. They had had to face the coal strike last year, but owing to the arrangements which had been entered into the effects had not been great. Mr. Beeton stated that the Company had been very much complimented on the quality of the light which they produced. Capital had been expended on new machinery, and the capacity of the station was now in excess of the immediate demand. At the end of the past year there were 28,429 lamps connected, and at the present time they could supply current for a further 5,000 lamps without an increase of plant. The capacity now was 45,000 8-c.p. lamps. With respect to the transfer of the northern area to the local authority, the local authority could deal with it more advantageously, and they had therefore cancelled that portion of the sphere of their operations. The Company had now obtained experience, and they could forecast their future operations. More lights had been connected during the year than in any other, with the exception of the first days, when the potential demand was great.

Mr. William Page, in seconding the adoption of the report, pointed out that during the four years' operations of the Company the profits had steadily increased, and he did not think the price per light could go down much more, it now being about 8s. 7d., as against 10s. a year or two ago. The great source of the improvement in the profits was due to the economy which had been practised at the works. He bore testimony to the excellent way in which the staff had worked.

In reply to Mr. Kember, the **Chairman** stated that they could not undertake to pay dividends on the preference shares half-yearly instead of yearly, but would try to do so. With respect to the debentures he expected that these would be renewed at a more favourable rate of interest.

The report was adopted unanimously, and on the motion of the **Chairman**, seconded by **Mr. William R. Davies**, it was decided to pay a dividend of 7 per cent. on £25,000 cumulative preference shares.

The **Chairman** said that Mr. Robert Hammond, having decided in December last to retire from contracting work and to confine himself entirely to consulting work, had withdrawn from all the Boards with which he was connected, and had retired from this Board. He would, however, act as consulting engineer to the Company.

Mr. W. F. Leese and Mr. W. R. Davies, who retired from the Board by rotation, were re-elected directors. Messrs. Theobald Bros., Miall, and Co. were reappointed auditors.

EASTBOURNE ELECTRIC LIGHT COMPANY, LIMITED.

The annual meeting was held last week, Alderman Boulton (chairman of directors) presiding.

Mr. Towner (the secretary) read the report of the directors, of which the following is a summary:

The gross profit for the year, after allowing a further sum of £400 for depreciation of machinery, plant, etc., is £1,981. 2s. 2d., of which sum £1,271. 3s. 8d. has been paid for interest on debentures and mortgages, leaving a balance (including £114. 5s. 2d. carried over from last year's accounts) of £824. 3s. 8d. available for dividend. The directors recommend a dividend at the rate of £5 per cent. upon the share capital (free of income tax), which will absorb £508. 10s., and leave a balance of £315. 2s. 8d. to meet the directors' remuneration, and to carry forward a surplus to the credit of the current year's accounts. The reserve fund to meet depreciation now amounts to £1,425. Last year the directors mentioned that the extension of the circuits to the Upperton and Old Town districts was under consideration, and as the suggestion met with the approval of the shareholders the matter has been carefully thought out, and it has been decided to carry it out. The Company's machinery, plant, and mains are in excellent condition. Upwards of 1,300 incandescent lamps have been taken during the year, and a contract entered into with the Eastbourne Town Council for the supply of five additional arc lamps to the Royal-parade, which are now running. The number of lamps at present in use are as follows: arcs, 27; incandescents of 10 c.p., 8,454; as against 21 arcs and 7,136 incandescents in use at December 31, 1892. Mr. James George Langham retires from the board this year, but is eligible for re-election. The auditors, Messrs. Hart Bros., Tibbets, and Co., also retire, but may be re-elected.

The **Chairman** said it was the first time in the annals of the Company they had a satisfactory report with an increasing amount of business and of income. For years past they had been working under great disadvantages—they had been working against apathy and against interests that had been too powerful for them to succeed as they could have wished. He thought, however, they had got over the difficulties now, and the report which the directors presented that day was a highly satisfactory one and reflected great credit on the officers and others connected with the administration of the Company. The gross earnings of the Company had been as follows: 1886, £1,679; 1887, £2,263; 1888, £3,529; 1889, £4,147; 1890, £4,736; 1891 (five quarters), £6,753; 1892, £5,463; 1893, £6,992. That, he thought, showed the Company was in very good fettle, and that they were doing their work well, and satisfactory to the public, because, if not, their increases would not have been so steady. The extension of the system to Upperton and Old Town had very much exercised the minds of the directors, and they believed that a large increase of business would accrue if they could carry out that extension, but, of course, they could not do it without money. They proposed to raise the necessary amount by debentures at 5 per cent., and they had approached the present debenture-holders, who had agreed that any new debentures should rank equal with those they held. He did not like to say

Digitized by Google

anything about himself, but he might tell them he was so satisfied with the stability of the Company that he had taken a thousand pounds' worth of the new debentures. What they wanted to do was to raise a sufficient sum of money from them on debentures to enable the directors to carry up the main to the Upperton and Old Town districts so as to get a large increase in their business and receipts. In conclusion, the Chairman proposed the adoption of the report.

Mr. Langham, in seconding the motion, said it was a great satisfaction to him, having interested himself in the movement from the commencement, to find that his prediction that the electric light was the light of the future had become true and was rapidly becoming more true every day.

The motion was unanimously passed, and on the proposition of **Mr. Langham**, seconded by **Councillor Skinner**, it was resolved to pay a dividend of 5 per cent.

Alderman Sutton proposed the re-election of Mr. Langham as director, and this was unanimously carried.

Mr. Hollins proposed that the sum of £200 should be voted to the directors for their services during the past year, and said he was sure all the shareholders must be grateful to those gentlemen for the way in which they had stood by the Company.

Mr. Hurst seconded, and the motion was adopted.

Messrs. Hart Bros., Tibbetts, and Co. were re-elected auditors.

An extraordinary meeting was then held, and the **Chairman** proposed: "That the present first debenture issue of £25,000, bearing interest at the rate of £5 per cent. per annum, be extended with the consent of the present holders of debentures of such issue to £35,000; and that the whole of such extended issue shall bear interest at the rate of £5 per cent. per annum, and that all the debentures forming part of such first issue of £35,000 shall rank *pari passu*, and without priority both as to principal and interest, whether the same shall have been issued prior to or after the date of this resolution."

Mr. Langham seconded, and the resolution was carried, and a vote of thanks passed to Alderman Boulton for presiding.

CHATHAM, ROCHESTER, AND DISTRICT ELECTRIC LIGHTING COMPANY, LIMITED.

The annual general meeting was held last week in the Board-room at the works, Whittaker-street, Chatham. The chairman (Mr. Henry Jasper) presided. The annual report was as follows:

"Your directors, in presenting the sixth annual report and balance-sheet made up to December 31, 1893, have great pleasure in drawing your attention to the continued marked progress of the Company, which now presents prospects of success much more definite than were entertained in the past. At your last general meeting your directors gave hopes that the new management would enable them to pay an interim dividend in June, 1893, and they beg to draw your attention to the fact that the profits made this year would have warranted their doing so. They have, however, decided for the present not to pay any dividend, as they consider that it will greatly add to the future benefit of the shareholders to carry the balance of revenue forward to a reserve fund. Your directors regret, notwithstanding the facility with which other electric lighting companies are obtaining debentures, that not sufficient of the first issue of the debentures of the Company, offered to the public in January last, have been taken up to enable them to proceed with the proposed extension of mains and plant. Could this proposed extension have been carried out, Mr. M. H. Hurrell, your managing director, considers your present profits (after paying interest on debentures) would have been considerably more than doubled this year. We must here call your especial attention to the fact that every promise made by him with regard to our profits has been fulfilled, and this notwithstanding the great loss we have sustained from being unable to take his advice and accept the low tenders for coal offered us before the coal strike of last year. Since the completion of the underground mains, which, however, only covers the same area as that covered by the late overhead system, a number of new customers have been connected, representing an increase of 6,580 candles, and your especial attention is also drawn to the fact that, with the exception due to the stoppage of the Gaiety Music Hall, we have not only retained every one of our customers, but the majority have, since the introduction of the meter system, considerably increased their number of lamps by upwards of 2,000 candles, thus showing their high appreciation of the light, both with regard to its superiority and its price compared with gas. A very considerable increased number of lamps has also been connected since the date of this balance-sheet, and our staff are still fully occupied with this work; but your directors regret to say that they are not able to do nearly as much in this way as might be done, nor can they carry out such, or any further necessary work of the Company, without raising further capital, either as ordinary shares or debentures. Your directors have under consideration the issuing of the first part of our first issue of debentures at a discount, to enable them to proceed with the necessary and pressing work. Mr. William King retires by rotation, but, being eligible, offers himself for re-election. Messrs. J. E. Ratcliff and G. F. Butts, the auditors, retire, and offer themselves for re-election."

The **Chairman**, in moving the adoption of the report, said he did not know that there was much for him to say, as the report embraced the whole of the Company's affairs, and he did not think he could enlighten them much more by details. The directors anticipated that a larger number of lights would have been taken up, but many had not cared to go to the expense of the installation. That matter had now, however, been vigorously taken up by Mr. Hurrell, their managing director, whose great experience enabled him to superintend the work and get the light installed at the very lowest possible cost. A large number of customers had adopted meters in preference to having the light supplied by fixed contract, and were thus able to economise, not paying for light unless it was consumed. The result had proved perfectly satisfactory, and several of the customers had put on additional lights in their establishments. It was expected that before the end of the present year the whole of the consumers would have adopted the system of supply by meter. Another advantage was the reduction in the cost of lamps through the royalties having expired. These things combined had tended to increase the demand for lights, as all of the changes had favoured the consumer. The Company were steadily rising in public favour and confidence. This Company could greatly extend its business with more capital, and the value and extent of their plant and machinery and their business were excellent security. Speaking of how much of their success was due to their managing director, he observed that the Company would have been in a far different position to-day had they such a manager from the first. The directors would have been warranted in recommending a 2½ per cent. dividend, but as money was wanted for extending their mains it was decided not to declare any dividend and to endeavour to get the debenture stock taken up. The earnings of the Company's station had been highly satisfactory, notwithstanding that they had been unable to act upon the managing director's excellent advice and buy up coal prior to the coal strike. When compared with other companies, their record throughout was a highly favourable one. He had much pleasure in moving that the report be received and adopted.

Mr. Church seconded this, and the report was unanimously adopted.

On the proposition of **Mr. Masters**, seconded by **Mr. Church**, Mr. W. King was reappointed a director.

Mr. Massey moved, and **Mr. Williams** seconded, that Messrs. G. F. Butts and J. E. Ratcliff be re-elected auditors. This was supported by the **Chairman** and carried.

HASTINGS AND ST. LEONARDS-ON-SEA ELECTRIC LIGHT COMPANY, LIMITED.

The annual meeting was held last week at the Brassey Institute, Claremont, Hastings, Mr. H. M. Baker, J.P., presiding.

The **Chairman**, in moving the adoption of the report, said that those who recollected the last meeting might remember that attention was called to the fact that they would have during the current year to call up a considerable amount of capital to carry on a larger and increased business. If they would compare the balance-sheet with that of last year they would find that they had called up £5,230 during the year, and that their revenue was increased from £4,276 to £5,390, or an increase of £1,114, which was a little more than 25 per cent. Although that was satisfactory as far as it went, it was only fair to say that it would have been very much more, but as he had explained on the last occasion, a considerable amount of expenditure had been incurred, which would undoubtedly be realised during the current year over the lighting of the whole of the Front Line. As they were aware, the full extent of the lighting was not to take place till midsummer. He took that opportunity of publicly stating the fairness with which the Corporation had met them in all their transactions with them. As regards the increase of the Front lighting, the Corporation represented to them that the gas company considered it only fair they should have proper notice to terminate their contract, and as three months of their last year would be very long days and short nights, they felt that the liberal manner in which the gas company had in times past treated them was such that they could not very well refuse the request of the Town Council to meet their views. The next thing he should like to allude to in the report was to his mind a very important one. That was that they thought it well, in the interests of the shareholders, to secure to themselves the services of Prof. Kennedy. After making every enquiry, they decided to appoint that specialist, and it had proved that their decision had been right. In the same paragraph of the report it went on to say that Prof. Kennedy had examined their plant and works generally, and had approved of everything that had been done. They had arrived at that stage in the history of the Company when their directors believed it would not do to rest on their oars and take things quietly. They believed that a great responsibility must be thrown upon their shoulders or upon some others. Having led them for several years through good report and bad report, they had now arrived at that condition that he did not hesitate in telling them that if they were in a position to supply the light they could sell half-a-dozen times as much as they did now. Up to the present time they had thought it advisable to move slowly, but their directors would have seriously to consider the best means to meet the increased demand which they were receiving on all hands when they wanted more capital. They had asked the shareholders for it, and they had got what they wanted, but whether they would go on in that slow way by degrees would be a matter they would have to consider, and that it would have to be considered very seriously he could assure them. They must not forget, as pointed out to Mr. Langham and himself by the officials of the Board of Trade, they had a very valuable concession in their provisional order, by which they had to supply the whole of that district, and under that provisional order there were certain conditions which sooner or later they would be called upon to fulfil. They had a very valuable property—no one could doubt that—and it was certain that the electric light must be the light of the future.

Digitized by Google

Mr. Shorter, who seconded the adoption of the report, thought the shareholders were thoroughly satisfied with the progress the electric light had made.

The report was then adopted, and a dividend of 5 per cent. declared.

The **Chairman** stated that Messrs. F. A. Langham, J. Reeves, sen., and J. Woodhams retired that year by rotation as directors, and they were all eligible for re-election.

The **Rev. J. W. Tottenham** proposed the re-election of the three retiring directors.

Mr. A. L. Ward seconded, and the motion was carried.

Messrs. Hart Bros., Tibbets, and Co. were re-elected auditors, and a vote of thanks accorded to the chairman for presiding closed the proceedings.

BUSINESS NOTES.

Ludgate-circus Post Office.—This new post office is being wired by Messrs. Spagnoletti and Crookes.

Western and Brazilian Telegraph Company.—The receipts for the week ended March 27 were £2,735.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 25th inst. amounted to £797.

Folkestone.—A meeting of the Town Council is to be held to consider a further report of the Electric Lighting Committee.

Waterloo and City Railway.—In reference to the Waterloo and City Railway Company, it is stated that the applications for shares are in excess of the number required.

St. Pancras.—The St. Pancras Vestry have accepted the tender of Messrs. Crompton and Co. for supplying engines and dynamos for the new King's-road station, at £6,917. 9s.

Joseph Mills and Co., Limited.—This Company has been registered with a capital of £2,000, in £1 shares, to acquire the electrical business now carried on by Joseph Mills at Sheffield, and to carry on and extend the same.

Dover.—The surveyor to the Town Council has received from the architect of the electric lighting station new plans giving a more elaborate description, and as the builders want to proceed with the work he has inspected the plans and recommended their adoption.

City and South London Railway.—The receipts of the Company for the week ending March 25 were £792, against £859 for the same period last year, or a decrease of £67. The total receipts for the first half-year of 1894 show a decrease of £80 compared with those for the corresponding period of 1893.

Lighting of Asylums.—In the estimate supplied to a committee of the Barony Parochial Board, Glasgow, the initial cost of lighting certain parts of Woodilee Asylum with electricity was given as £562, as against £440 for gas, and the annual cost at £98, as against £92 for gas. These estimates were brought before the Parochial Board, and it was resolved to fit up the institution with gas.

Messrs. Baxendale and Co.—This Company inform us that they have just secured the following contracts: complete electric lighting plant for the Bromley-street Mills, Manchester; complete wiring for Corporation supply at the Wesleyan Chapel, Nelson; Messrs. W. Thompson and Co., Spring-gardens, Manchester, complete wiring of both establishments for Corporation supply; and Messrs. Smallman's new restaurant, Manchester.

Rebey and Co., Limited.—The estate of a deceased partner (the late Mr. William Mackinder) of this well-known firm of engineers offers for subscription by tender 2,880 fully-paid shares of £10 each. Forms of application can be obtained of the bankers and of the auditors of the Company, or of Messrs. Andrew, Wood, and Co., solicitors, 8, Great James-street, Bedford-row, London, and of Messrs. Andrew and Trotter, solicitors, Lincoln, of whom all further information may be obtained.

Building Trades' Exhibition.—At the Building Trades' Exhibition, which closes to-morrow (Saturday), at the Agricultural Hall, Islington, Mr. Harry South, of 10 and 12, Garrick-street, Covent Garden, is lighting about 90 16-c.p. incandescent lamps. The current is supplied by a Crompton dynamo driven by a Tangyes gas-engine. Messrs. Baird, Thompson, and Co. make a good display of ventilators and ventilating fans, the latter including a fan driven from its own engine.

Islington.—At a meeting of the Vestry last week the clerk read a letter from the solicitor with reference to the purchase of the land for the electric lighting station (Holloway-road site). It stated that the vendor's solicitors had refused to extend the time fixed for the completion of the purchase, 23rd inst., although the abstract was only delivered on the 9th inst., and suggested that a cheque should be drawn for £7,650, payable to the Great Northern Railway. The matter was referred to the Finance Committee.

Bromley.—At a meeting of the Electric Lighting Committee of the Local Board a letter was read from Mr. F. Stevens, clerk to the Beckenham Local Board, enquiring whether the Bromley Local Board would be willing to appoint a small committee to confer with a similar committee of the Beckenham Local Board as to the advisability of constructing electric lighting works to supply the two towns. The committee recommended that Messrs. Davis, Selby, and McIntyre be appointed a sub-committee to confer with the Beckenham members on the subject. This recommendation was adopted.

Country-House Lighting.—The contract for the electric lighting of Merrow Grange for Mr. F. Baring-Gould has been placed in the hands of Messrs. Allpress and Co., of 55, Victoria-street, Westminster. The dynamo will be run by an oil-engine, and accumulators will be used. The engine-house will be built some distance from the mansion, and besides the electric lighting two sets of pumps will be driven by gearing off the engine for delivering into tanks, placed in the house, soft water from an underground reservoir, and hard water from a well, the latter being passed through a Porter-Clark softener.

Lighting at Cardiff.—At a meeting last week of the Lighting and Electrical Committee of the Cardiff County Council, Mr. W. H. Massey (electrical engineer) reported that 14,385 yards of pipe work had been finished, leaving 2,500 yards to be put down. The light will be available in May. Mr. Harpur (borough engineer) said that the committee might consider the propriety of extending the area into Tredegarville, where there were many people who wanted the light. Councillor Brain asked what would be done if someone outside the district applied for the light, and Mr. Massey stated that it was within the right of anyone in the borough to apply for the extension of the mains, and terms were fixed which were fair to both parties.

Hanley (Staffs.).—The following tenders were received for lighting the Higher Grade Schools, Hanley, by electricity, for the Hanley School Board:

Ball and Co., Bristol	£661	7	3
Brush Electric Company, London	588	19	9
Laing, Wharton, and Co., London	586	8	9
Fowler, Lancaster, and Co., Birmingham	557	13	0
Maunsell Mercier and Co., Manchester	475	10	0
J. Blackburn, Nottingham	466	14	8
Spagnoletti and Crookes, London	436	17	0
Verity and Sons, Manchester	398	11	6

The tender of Messrs. Verity and Sons, Manchester, has been accepted.

Industrial Exhibition at Bingley Hall.—The National Trades' and Industrial Exhibition was opened at Bingley Hall, Birmingham, on Saturday. The hall is lighted by the Walsall Electrical Company in conjunction with Messrs. Tangyes. Amongst the machinery, Messrs. Robey and Co., of Lincoln, show their improved gas-engines; Messrs. Tangyes, Limited, have on view gas-engines, one of which is driving a dynamo for the electric lighting of the hall, which they are carrying out in conjunction with the Walsall Electrical Company, who occupy the adjoining stand with a number of electrical appliances for private installations. Other electrical engineers represented are Messrs. Langstone, Young, and Co., Coleshill-street; Mr. J. A. Ewins, Scholefield-street; and Messrs. T. L. Hemming and Co., Snow-hill.

The Deansgate Hotel, Manchester.—Messrs. Maunsell Mercier and Co., of 5, Deansgate, Manchester, have secured the contract for wiring, fittings, and complete plant for about 600 16-c.p. lamps for this hotel. The generating plant will consist of two 30 b.h.p. "Premier" gas-engines and two dynamos driven from countershafts. To minimise the risk of failure (no gas being put in) two circuits will be run all over the building, and the lamps will be alternately on each circuit. The main switchboard will have two voltmeters, two ammeters, two double-pole main switches, and 18 two-way branch switches, so that any circuit may be switched on to either machine. Provision will be made in the engine-house for a spare engine and dynamo. The architects are Messrs. Moffat and Bently, of Whitehaven.

Electricity and Photography.—Messrs. R. and S. J. Lawson, of Railway-arcade, Shepherd's Bush, W., send us the following cutting: "Electricity plays a very important part in the photographic world to-day. Not only are studios and showrooms illuminated by the incandescent lamp—even the darkroom is invaded, and most lampmakers now lay themselves out to supply some contrivance for filtering the light through a ruby or orange medium. Messrs. Shippey Bros., of 13, King-street, Cheapside, adopt the plan of encasing the bulb in an outer glass case, and filling the interstice with a deep ruby fluid, through which the light passes in an agreeable fashion. The lamps are made in all voltages, from 1 c.p. upwards; and special holders have been devised to accommodate the double bulb."

Church of St. Nicholas Cole-Abbey.—This City church is lighted by electricity, the contract having been carried out by Messrs. Henry F. Joel and Co. The main body of the church is lighted by 11 200-c.p. incandescent lamps, with the lamp bulbs obscured or frosted to soften the light, giving an effective light of 150 candles. The lamps are fitted in artistic glass shades, with wrought-brass scrolls, designed by Mr. J. Aldam Heaton. The lamps are pendant lamps, and are so arranged that they can be lowered from the roof for cleaning or other purposes. Each lamp has a controlling switch in the vestry, where the verger turns them "on" or "off" as previously agreed upon with the rector. There is one 200-c.p. lamp in a globe outside the principal entrance, and 16 smaller lamps of 16 c.p. distributed in the vestries, entrances, etc.

Costly Light.—Under this heading "Pgh" has written to the *City Press* as follows: "Is it not time for one of our representatives to move the Corporation to take the opinion of the citizens on the subject of excessive gas and electric lighting charges? You are doubtless aware that parishes outside the City are holding meetings in condemnation of the Gaslight and Coke Company charging their customers 3s. 1d. per thousand on the north side of the Thames, and 2s. 5d.—or about 27½ per cent. less—on the south side. It is also worthy of note that in St. Pancras the

Digitized by Google

charge for electric light is 6d. per unit, while in the City it is 8d., or 33 per cent. more. I think you will agree that the citizens have a right to expect their representatives to make an earnest effort to protect the interests of their constituents by seeing that gas and electric light are given to them at the lowest possible price."

Bournemouth.—At a meeting of the Town Council last week the Lighting Committee, having considered the report received from Major Cardew as to the accident by which a horse was killed, recommended that the town clerk should write to the Board of Trade asking what steps had been taken by the electric supply company towards carrying out the suggestions contained in the report. The same committee reported the receipt of a letter from Messrs. Martin and Leslie, parliamentary agents, stating that the Board of Trade proposed to issue the license to the Town Council in the form which they enclosed with the present letter. The committee recommended that a voltmeter be purchased and fixed at the municipal buildings at an estimated cost of £15. The reports were adopted, but later in the meeting the Mayor announced that Major Cardew had arrived in Bournemouth that day to enquire into certain matters which had recently occurred in connection with the working of the electric light system.

Ignition Tube for Gas-Engines. — Bearing the title of "Wellington's Indestructible Ignition Tube," a new tube for gas and oil engines has been introduced by the Indestructible Ignition Tube Syndicate, Limited, of 100c, Queen Victoria street, London, E.C. The tubes are made in different shapes and sizes so as to suit various gas-engines. Some tubes are provided with a collar at their base, whilst others have a trumpet-shaped end A special gunmetal union is provided for each type of tube, and the joint is made with a little red lead. The tube is the result of research into the various silicacious earth combinations, which, when properly arranged, form a mixture having great refractoriness, combined with the power of resisting pressure at high temperatures, and of acquiring a white heat almost simultaneously. The makers claim that the endurance of this tube has been proved at 15 months' continuous working ; that it only requires two minutes to attain a bright red heat ; and that it can be fixed to any gas-engine.

Assessment of Electric Light Works.—At a meeting last week of the City of London Union, the Assessment Committee reported that their attention had been called by the vestry clerks of certain parishes to the effect that the electric company's works were in a very forward condition, and should, in their opinion, be valued for the purposes of assessment. The committee had decided that the work was in the nature of a public undertaking, and that the valuation by each parish separately would necessarily be of an unsatisfactory and very costly nature. They recommended that Mr. Walter Barnett, of Winchester House, should be appointed to value the undertaking as it now stood, supply detailed maps or plans, together with a detailed report of all buildings, mains, works, and the whole of the mains and any other property belonging to the company ; attend upon the committee and upon any of the vestry clerks and overseers of the various parishes, attend at court if necessary in the event of appeal, and ascertain the proportion properly chargeable to each of the 112 parishes in the union, at an inclusive fee of £420. The report was agreed to.

Shiplighting.—There has been launched from the yard of Messrs. W. B. Thompson and Co., Limited, Dundee, a screw-steamer named the "Fingal," for passenger and cargo trade between Leith and London. The vessel is 290ft. 6in. long, 35ft. beam, and 18ft. 2½in. deep. The state-rooms are handsomely furnished, and have each communication with the steward's department by means of electric bells. The steam steering-gear engine is controlled from the bridge, and telegraphs communicate with the engine-room. The electric light equipment is supplied by Messrs. W. C. Martin and Co., Glasgow, and will be one of the most complete ever fitted on board a passenger steamer of the size of the "Fingal." The installation will include two sets of direct-acting engines and dynamos. Each section of the ship will be lighted by interchangeable appliances from either dynamo, so that a duplicate supply is available in the event of any mishap. The fittings for the saloon and social hall are of choice design, in rich cut-glass shades and lamps, tinted in a variety of colours, and the promenade decks and other parts of the ship will all be brilliantly illuminated. The mast and side lights will be Martin's patent duplicate electric system, and tell-tale indicator on deck bridge.

Buckingham.—At a meeting of the Town Council last week, the Mayor said the first question on the agenda was to consider the recommendation of the Lighting Committee to the effect that the gas company be offered 4s. 2d. per 1,000 cubic feet for gas to be supplied by them during the current year, being the price charged in neighbouring towns. Alderman J. W. Thorpe rose and proposed that the recommendation be adopted. Councillor Barnes seconded the proposition. Councillor Holland thought it would be advisable to hear the terms to be offered by the electric light company before they proceeded with this proposition. Other members thought otherwise, but there being no amendment, the proposition was declared carried. The Mayor said the next item was to consider the tender from Messrs. Parr and Gillies for electric lighting of certain lamps. The town clerk produced the tender, which offered to continue to light the lamps over the entrance to the town hall and the post office, and also the eight others in and adjoining the Market-square, at the rate of long-time lamps £1. 4s. each, and short-time lamps 12s. 8d. each, per annum. In reply to a question, the Mayor said the gas company were paid £1. 10s. for long-time and 14s. 7½d. for short-time lamps. Councillor Holland said he had no objection to the lighting of the lamps by electricity, but he did not like the lamps being confined to the specified area, because in case of a mishap the whole of that part of the town would be in darkness. Councillor F. Higgens moved that the tender be accepted, and Alderman J. W. Thorpe seconded the proposition, which was carried.

Result of Cheltenham Tenders.—The following tenders were received by the Corporation for supplying and erecting engines, dynamos, and boilers at the central station :

	Whole.	A.	B.	C.
Laing, Wharton, and Down (B. and L.)	£4,964	£360 0	£4,002 0 0	£682
Siemens (Belliss, D.)	4,360	365 0	3,450 0 0	590
Siemens (Willans, D.)	4,610	365 0	3 695 0 0	590
J. Fowler and Co. (Fowler, R.)	4,500	377 0	3,612 0 0	575
Johnson and Phillips (B. & L., B)	4,307	345 0	3,280 0 0	682
Crompton (B. and L., R)	4,100	430 0	3.060 0 0	660
Crompton (D. P. and R.)	4,125	430 0	3,100 0 0	660
Crompton (Belliss, R)	4,180	430 0	3,163 0 0	660
Crompton (Belliss, D.)	4,170	430 0	3,160 0 0	660

Electric Construction Corporation	—	—	3,400 0 0	—
McLaren (McLaren, R.)	—	—	3,322 10 0	—
Mather and Platt	—	—	3,255 10 6	—

Note.—B. and L. is Browett and Lindley engines, D is direct driving, R is rope driving, and B is belt driving. The tenders of Messrs. Siemens Bros., at £4,245, and of Messrs. Galloways, Limited, at £877. 10s., have been accepted.

Rockhampton Gas and Coke Company, Limited.—The report of the directors for the half-year ended December 31 last congratulates the shareholders upon the business done. Notwithstanding the general depression that has prevailed, necessitating economy on the part of the Company's customers in their use of the gas and electric light, the profit is greater than for the corresponding half of last year. The gas operations show a profit of £2,006. 13s. 9d. The electric light operations show an actual loss of £21. 9s. 4d., to which is added £294. 2s. 11d., interest upon the capital invested in the electrical plant and buildings, making a debit balance of £315. 12s. 3d. The net profit arising from the whole of the Company's business is £1,691. 1s. 6d. The lighting of the Fitzroy Bridge with powerful electric arc lamps, referred to in the last report, is now in operation. Numerous applications from business people have been made for high-power arc lamps for outside illumination, and the directors are importing suitable lamps for this purpose. A section of the Company's amended Act provides that the retention of the power to supply Rockhampton with the electric light is dependent upon the Company commencing operations and installing the light to the satisfaction of his Excellency the Governor-in-Council, and of the Council of the Municipality of Rockhampton, within five years of the date of the passing of the said Act. The directors report that the Governor has intimated his satisfaction and approval of the work done by the Company in this direction, and the Rockhampton Municipal Council has passed a resolution expressive of its entire satisfaction of the manner in which the light has been installed. The special conditions of the Act having therefore been complied with, the Company's powers in respect of electric lighting in Rockhampton and North Rockhampton are now finally confirmed. The directors, after careful consideration, are of opinion that the debit balance of the electric light operations can fairly be written off the general reserve fund, and they recommend this being done. They recommended that a dividend at the rate of 10 per cent. per annum, amounting to £1,997. 4s. 4d., be paid out of the profit arising from the gas operations for the half-year.

Lighting of Guildford.—A meeting of the Town Council was held last week to further consider the question of the electric lighting of the borough, the subject having been adjourned from the previous Tuesday. Since the last meeting the General Purposes Committee had held another meeting, and the town clerk (Mr. F. F. Smallpeice) read the following report: "The General Purposes Committee report that since the meeting of the Council held on the 13th inst. they had given further consideration to the question of the application which is now before the Board of Trade for the granting of a provisional order for electric lighting in the borough, and they are still of opinion that the supply of electricity in the borough should be in the hands of the local authority. As the committee are led to believe that the promoters are willing to have clauses inserted in the provisional order which will enable the Town Council to take over the undertaking at some future time on equitable terms, they recommend the Council to agree to withdraw their opposition to the granting of the provisional order on condition that clauses to the following effect are inserted therein: (1) a clause empowering the local authority to acquire the undertaking for a sum not exceeding £350 at any time within three months after the commencement of the order; (2) a clause providing that in the event of the Town Council exercising the power given them by the preceding clause, the period for carrying out the compulsory works be extended to three years from the commencement of the order ; (3) a clause providing that the local authority may acquire the undertaking after the expiration of the period above mentioned and before the expiration of a period of 42 years from the commencement of the order on terms similar to those inserted in the Oxford provisional order, but with a modification that the payment of the purchase-money or consideration for the undertaking in such event shall be made in cash and not in bonds or stock." The Mayor moved the reception and adoption of the

Digitized by Google

report, which was seconded. Councillor Wrist moved as an amendment that Clauses 1 and 2 of the report be omitted. This was seconded, and after some discussion the amendment was lost by eight votes to six. The resolution was then put, and was lost by seven votes to five. Alderman Allen said that if the opposition were carried forward the probability was they might get a reduction of the 42 years; whereas if there were no opposition they might find that they could not in the interest of the ratepayers obtain the purchase under 42 years. He proposed that the town clerk be instructed to carry forward the opposition, notice of which has been given to the Board of Trade. Alderman Swayne seconded, and the motion was carried.

Inauguration of the Oldham Station.—This station has just been set in operation, the ceremony being performed by Miss Smith, daughter of the Mayor. There was a numerous attendance, including the Mayor and Mayoress, Alderman Hall, Councillors Bolton, Shaw, Nield, Harrop, Ingham, and W. H. Holt, Prof. Kennedy, Mr. Newington (resident engineer), Mr. H. Andrew (gas and water superintendent), and Mr. J. Chadwick (gas manager). After the current was turned on, the Mayor gave an explanation of the scheme. He said that in 1890 application was made by the Corporation for a provisional order to enable them to supply electricity. The provisional order passed the Board of Trade in due course, and on August 4, 1890, was confirmed by Parliament. A committee was then appointed to obtain information from other towns with respect to the supply of electricity, and an electrical expert was engaged to advise the committee as to the best scheme to adopt, and Prof. Kennedy was retained for this purpose. In 1892 an application was made to the Local Government Board to confer powers upon the Corporation to borrow money to carry out the requisite works for supplying electricity, and a Local Government Board inspector held an enquiry in August of that year, and in the September following the Local Government Board approved the scheme and sanctioned borrowing of £27,000 for electric lighting purposes, repayable in 25 years. Tenders were obtained for the undermentioned works, and the following were accepted: for the erection of the electric lighting station, Messrs. S. and J. Smethurst; dynamos, engines, fittings, switchboard, instruments, and connections, Messrs. Charlesworth, Hall, and Co.; steam-boilers, the Oldham Boiler Works Company; batteries, etc., the Crompton-Howell Electric Storage Company; economisers, Messrs. Green and Son; insulators, Messrs. Doulton and Co., London; and Messrs. Siemens Bros., Limited, and Henley's Telegraph Works Company for cables. The laying of the mains and the construction of the conduits in the streets was executed by the Corporation under the supervision of their electrical engineer, Mr. Newington, Mr. Chadwick, the gas manager, and Mr. Herbert Andrew, the superintendent of the gas and water departments. The Mayor then read a report which had been prepared by Prof. Kennedy. In conclusion, his Worship remarked that the total tenders amounted to £13,678. 10s.; the making of street mains and conduits, £6,000; service lamps, meters, etc., £600; balance to pay, £5,214; or a total cost of £25,070. It had been suggested that they might utilise the steam generated at the destructor, but that was a matter the committee could consider at some future time. On the motion of Prof. Kennedy, seconded by Councillor Taylor, a vote of thanks was passed to Miss Smith and the Mayor, and the members of the committee then visited the different parts of the town where lamps had been fixed.

PROVISIONAL PATENTS, 1894.

MARCH 19.

5690. **Improvements in connection with microphones.** Hermann Oppenheimer, 55, Redcross-street, London.

5721. **New or improved process and apparatus for the electrolytic decomposition of common salt.** Castle Smith, 54, Fleet-street, London. (Gersdorf Jorgensen, Norway.)

MARCH 20.

5728. **Adapting electromotors to dental purposes.** William Routledge, 46, Low Friar-street, Newcastle-on-Tyne.

5735. **Improvements in electrical switchboards.** Edward James Paterson and Claude William Hill, European Works, Pownall-road, Dalston, London.

5754. **An improvement in electrical arc lamps.** William Harding Lauder, 33, Blessington-street, Dublin.

5796. **Improvements in underground conduit systems for electric railways.** Herluf August Frederik Petersen, 18, Southampton-buildings, Chancery-lane, London. (Complete specification.)

5806. **An improvement in dynamo-electric machines and apparatus for driving them.** Arthur Salisbury Baxendale, 28, Southampton-buildings, Chancery-lane, London.

5807. **A duplex electrical safety fuse.** The Edison and Swan United Electric Light Company, Limited, and Charles Faraday Proctor, 28, Southampton-buildings, Chancery-lane, London. (Complete specification.)

5816. **Improvements in electrical measuring instruments.** Henry Harris Lake, 45, Southampton-buildings, Chancery-lane, London. (Edward Weston, United States.) (Complete specification.)

MARCH 21.

5863. **Improvements in fuse-boxes for electricity supply mains.** Henry Reason, 111, Gloucester-road, Brighton.

5913. **Improvements in alternators.** John Smith Raworth, 46, Lincoln's-inn-fields, London.

5917. **Improvements in and relating to telephone and telegraph systems.** Sir Charles Stewart Forbes, Bart., 45, Southampton-buildings, Chancery-lane, London.

5918. **Improvements in arc lamps.** Samuel Sealy Allin and William Henry Wood, 52, Woodstock-road, Bedford Park, London.

5921. **An improved telephone combination.** Sir Charles Stewart Forbes, Bart., and the Domestic Telephone Company, Limited, 21, Finsbury-pavement, London.

5922. **An improved automatic electric machine.** Alfred Howard, 10, Clifford's-inn, London.

5931. **Improvements in electrically-propelled common road vehicles.** Ernest John Clubbe and Alfred William Southey, 53, Chancery-lane, London.

5932. **An improvement in electrically-propelled vehicles.** Ernest John Clubbe and Alfred William Southey, 53, Chancery-lane, London.

MARCH 22.

5971. **Improvements in apparatus for the use of the electric light for photographic purposes.** Andrew George Adamson, 154, St. Vincent-street, Glasgow. (Complete specification.)

5989. **Improved method of and appliances for manipulating search-light projectors.** William Elworthy, 73, St. Stephen's-road, Upton Park, London. (Complete specification.)

6028. **An improvement or improvements in electro-dynamo machines and in electromotors.** Samuel Jevons, 7, Staple-inn, London.

6046. **Improvements in the methods of effecting the electrolysis of saline solutions.** Louis Alphonse Paul Liénard and Henri Eugène Albert Liénard, 40, Chancery-lane, London. (Date applied for under Patents, etc., Act, 1883, sec. 103, 22nd September, 1893, being date of application in France.) (Complete specification.)

6057. **Improvements in electrical conductors and in the method of making connections between electrical conductors.** Henry Edmunds, 47, Lincoln's-inn-fields, London.

MARCH 24.

6089. **Improvements in the means of protecting electrical conductors.** John Augustine Kingdon, 29, Marlborough-hill, St. John's Wood, London.

SPECIFICATIONS PUBLISHED.

1893.

2740. **Electric arc lamps.** Rathbone.

4685. **Recording and reproducing tapes for electrical ticker machines, etc** Bott.

6170. **Earthenware electric switches, etc.** Hollins and Meir.

7082. **Brackets for electric lighting, etc.** Ketley.

7594. **Electrolytical decomposition of chlorides.** Lyte.

8571. **Cells for electric batteries.** Emery.

8812. **Telephone indicators.** Abel. (Soc. Générale des Téléphones Réseaux Téléphoniques et Constructions Electriques.)

8958. **Applying electricity to the body.** Rigola.

9627. **Electric light fittings.** Faraday.

9864. **Electric switches.** Evered and Watson.

20816. **Connectors for electric conductors.** Keithley.

23881. **Heating metals electrically.** Thompson. (Coffin.)

24271. **Telephonic apparatus.** Bonnard and Piat.

24274. **Electrolytic decomposition of metallic salts.** Kellner.

1894.

666. **Holders for incandescent electric lamps.** Evans.

2007. **Electric switch.** Edison and Swan United Electric Light Company and Proctor.

NOTES.

Telephony in Stuttgart.—A full night telephonic service is to be established here during the summer.

Carborandum in France.—Works are shortly to be erected in France for the manufacture of carborandum.

The Brussels Exhibition.—It has been decided not to hold the international exhibition at Brussels until 1896.

Society of Arts.—On Monday, at 8 p.m., the second Cantor lecture on "Photometry," by Captain W. De W. Abney, C.B., F.R.S., will be delivered.

Electric Tramway at Stuttgart.—The local authorities have approved of the introduction of electric traction on the tramway lines of Stuttgart.

Personal.—Mr. A. B. Blackburn, M.I.C.E. (late with Messrs. Mather and Platt, Limited), has been appointed chief engineer to the Electric Construction Company.

Private Bill Legislation.—The Charing Cross, Euston, and Hampstead Railway Bill will be dealt with by the Examiners on Standing Orders to-day (Friday).

Berlin.—The Berlin Electricity Works are making rapid progress with the laying of electric light cables in the new districts for which they have received powers.

Electric Tricycle.—The King of the Belgians, who met with a slight accident on Wednesday when riding a bicycle, is now having constructed a tricycle to be operated by electricity.

Lighting of Markets.—The Crawford Markets, in Calcutta, are to be lighted by electricity. The current will be supplied by a Silvertown dynamo driven by a 25-h.p. compound semi-fixed engine.

A Large Railway Contract.—An extensive contract has been made by the Nassau Electric Railroad Company of Brooklyn, N.Y., for the construction of 100 miles of street railway in Brooklyn and the country towns.

Electrical Exhibition at Leipzig.—In view of the second general meeting of the Union of German Electricians, which is to take place at Leipzig, an electrical exhibition is to be held there in the Crystal Palace from June 8 to 17.

Explosion at Nantes.—On Wednesday evening, according to a yesterday's telegram from Paris, an explosion of gas occurred in connection with the underground electric light mains at Nantes. Three persons were injured, one rather seriously.

Electric Traction at Hamburg.—The Hamburg electric tramway was formally opened on Friday. The line is worked on the Thomson-Houston system, and has been constructed by a Berlin company. There are 21¾ miles of line and 42 cars.

Cost of a Provisional Order.—The Bridgend Chamber of Trade have decided to obtain legal opinion on the action of the Local Board in charging the costs of a provisional order for the electric lighting of the town—amounting to over £200—on the current rate.

Not in a Hurry.—A French weekly electrical paper dated 1st inst. records that trials were made of the Heilmann electric locomotive on February 2. It is to be hoped that no dangerous results will ensue from the haste made by the staff to discover this item of "news."

Students of the Institution.—A students' meeting of the Institution of Electrical Engineers will be held this (Friday) evening at 28, Victoria-street, S.W. A paper will be read by Mr. A. F. Berry, entitled "Notes on Alternate-Current Transformers." Mr. W. M. Mordey will take the chair.

Charges for Current at Hull.—The Electric Lighting Committee of the Hull Corporation have decided to reduce the charge for the supply of electrical energy to consumers from 7d. to 6½d. per unit. The supply of current for motive-power purposes has been fixed at 5d. per unit.

Electrical Exhibition at Budapest.—The authorities of the Hungarian *Handels Museum* are arranging to hold from May 27 to September 30 next an electrical exhibition at Budapest. It main object is to show the various machines employed in small industries to which electromotors are applicable.

Telegraph Department.—Mr. A. Morley, replying in the House of Commons on Tuesday to a question by Mr. Macdonald, said the Departmental Committee upon the working of the Telegraph Department were now considering their report, and he had reason to believe that it would be in his hands in a few weeks.

Electric Tramway at Stockholm.—Portions of the electric tramway between Stockholm and Djursholm have been several times tested with satisfactory results on the whole, although some alterations in details have been found necessary. The line has not yet been officially taken over, but the installation is completed.

A Competition for Electricians.—The Swiss Association of Electricians have inaugurated a prize competition of £80 for the best critical paper on the regulations in connection with house installations and for the establishment of a scheme of normal specifications. Unfortunately, only Swiss electricians are allowed to compete.

Electric Lighting of Railway Carriages.—The Association of German Railway Managements has come to the conclusion that at present there has not been sufficient experience to enable a definite decision to be arrived at as to the efficiency and economy of electric lighting in railway passenger carriages. The public, however, has no doubt as to the efficiency.

Electric Railway for Vienna.—The Länder Bank and the Vienna Tramway Company are combining for the formation of a large Viennese transit undertaking, with a capital of from £2,000,000 to £3,000,000. This is required for the construction of an electric ring railway, and the present tramway company will be incorporated with the new concern.

Electromotors for Small Industries.—In the town of Esslingen the advantage of the use of electromotors in small industries is evidently appreciated. According to the *Elektrotechnische Zeitschrift*, 34 electromotors of a total of 133 h.p. are in use there. Of these 11 are used for metal-working, 10 for wood-working, three in graphic trades, three in chemical trades, two each by butchers and tanneries, and one each in dyeworks, ropeworks, and by a goldsmith.

Northern Society of Electrical Engineers.—A meeting of this society will take place on Monday next, the 9th inst., at the Palatine Hotel, Hunt's Bank, Manchester. The discussion will be continued on Mr. Rider's paper, entitled "Notes on Designing a System of Underground Electric Light Mains," and on Mr. Clirehugh's paper on "The Various Systems of Underground Mains and Methods of Laying Same." A paper will be read on "Electricity Meters," by Mr. R. P. Wilson.

Handling of Steel Billets by Electricity.—The transmission of power by electricity is now in operation at the works of the Illinois Steel Company, Joliet, Ill., for a variety of purposes. One application comprises an electrical apparatus employed to load steel billets on flat cars with the

Digitized by Google

minimum amount of manual labour. Another recently introduced means of electrically using power at the same establishment is exemplified in two electro-hydraulic ingot charging machines used in the heating-room.

Oil and Petroleum Engines.—A paper on oil and petroleum engines was read before the South Staffordshire Iron and Steel Works' Managers on Saturday evening, at Dudley, by Mr. H. M. Waynforth, A.M.I.C.E. (demonstrator in engineering, Mason College). The author stated that much attention was now being given to the application of oil-engines for agricultural purposes, barge and launch propulsion, electric lighting, and pumping, and that the results obtained were said to be highly satisfactory.

Altrincham Electric Supply Company.—The Altrincham Electric Supply Company, Limited, the registration of which is announced in another column, is inviting subscriptions to an issue of 25,000 ordinary shares of £1 each. The Company has been formed to undertake the supply of the electric light in Altrincham, Bowdon, Dunham Massey, Hale, and adjoining districts. The offices are at Temple-chambers, Brazennose-street, Manchester, and the subscription list closes on or before Tuesday next, the 10th inst.

Telephony in Bohemia.—Arrangements have been made for the establishment during the present year in Bohemia of telephone systems in Beraun, Brandeis, Franzenbad, Friedland, Komotau, Kralup, Kreibitz, Lobositz, Marienbad, Melnik, Nixdorf, Raudnitz, Roztok, Schlau, Trautenau, and Weipert; and of interurban lines between Prague and Tetschen, *viâ* Roztok, Kralup, Melnik, Raudnitz, Leitmeritz, Lobositz, and Aussig; and between Brüx and Komotau, and between Reichenberg and Friedland.

Oullins.—Work in connection with the electric tramway at Oullins, near Lyons, is being actively pushed forward, workmen being employed night and day in laying the rails and fixing the posts for the conductors. There are to be eight self-contained cars, each carrying 40 passengers. These are being furnished by the Compagnie Française du Matérial de Chemin de Fer. Each car has two electromotors of a combined power of 35 h.p. Lighting will be effected by three internal and two external incandescent lamps.

Ulm.—The local authorities have decided to build an electric supply station which is not only to furnish current for lighting purposes, but also for an electric tramway. The work will be carried out by Messrs. Schuckert and Co., of Nuremberg. The company will receive a 50 years' concession from the town, paying over to it a certain percentage of the receipts. The town may, however, take over the works at the expiration of 10 years, or at subsequent periods of five years, on paying various sums of money which have been set down in the contract.

Lecture.—A lecture on the subject of electrical forging and welding was delivered on Saturday evening before the Sheffield Society of Engineers by Mr. T. Scott Anderson, A.M.I.E.E. Samples of welding, forging, hardening, and tempering were exhibited, and the lecturer closed with the remark that what was necessary now was for the manufacturer to make known his difficulties in accomplishing certain work, and there was little fear that electricity would help him over those difficulties, and that sooner or later it must take an important place in all our industries.

The Theatrophone and the Volunteers.—Amongst the amusements provided at Canterbury during the recent visit of the volunteers was an entertainment by means of the telephone, which had just been completed between London and that city. The National Telephone Company took the opportunity of experimenting with the wires by connecting the London music halls with the premises of Councillor Lukey, the mayor, and some of the leading citizens. Besides this a large number of volunteers took advantage of the opportunity.

Stirling.—The Stirling Town Council, which some days ago resolved by a majority not to oppose the application of the Caledonian Electric Supply Company for a provisional order, have had the matter again before them at a special meeting. On the recommendation of the Electric Lighting Committee, they resolved to decline to withdraw their opposition to the order of the company, and decided to request the Board of Trade to withhold their consent to the order on the ground that the company now refuse to grant to the Council the terms they had previously offered.

Commercial Exhibition in South Africa.—A permanent exhibition in South Africa of samples and specimens of British goods and manufactures is being organised by Messrs. Hannan and Co., of 144, Leadenhall-street, E.C. It is proposed to make the exhibition a permanently active centre for the furtherance of British trade and trading interests, to gather together a collection of British machinery and commodities of a widely varied character, and bring the same immediately to the notice of buyers generally. The headquarters of the exhibition will be at Johannesburg.

Universal Index to Technical and Scientific Literature.—A weekly publication, entitled the "Universal Index to the World's Technical and Scientific Literature," is about to be issued. It will contain a classified list of all technical and scientific periodicals, arranged according to the places where they are published, the terms of subscription, and a full list of their contents, and a list of books and other publications dealing with the same subject. At the end of the year an index of subjects and authors will be added to each part. Communications may be addressed to the editor of the "Index," at Lenaugasse 5, Vienna (VIII.).

Electric Towing on Canals.—A permit for 50 years has been granted to the Cataract General Electric Company authorising it to enter upon all canal lands of the state for the purpose of constructing either on or over or under either canal bank a system for propelling canal boats by electricity, without interference with the present method of operation. The company must have its plant for operating boats by electricity in operation on the Erie Canal between Buffalo and Albany within three years from date. The company will obtain its power at Niagara Falls, from the Niagara Power Company, and transmit it to Albany along the line of the Erie Canal.

Central London Railway.—The Standing Orders Committee of the House of Commons met on Tuesday to consider a report from the examiners to the effect that the Central London Railway Company had failed to comply with the standing orders in respect of their petition for leave to introduce a Bill to extend the time within which to construct this railway. The proceedings of the committee were conducted in private, but it was announced that the committee had decided to dispense with the standing orders not complied with. In the event of this Bill being sanctioned, the time for completing this line will be extended until June 28, 1900.

The Institution.—A meeting of the Institution of Electrical Engineers will be held on Thursday next, the 12th inst. The paper read at the previous assembly, on "The Best Resistance for the Receiving Instrument with a Leaky Telegraph Line," by Prof. W. E. Ayrton, F.R.S., past-president, and Mr. C. S. Whitehead, M.A., will be

Digitized by Google

discussed. Papers on the following will be read: "Transparent Conducting Screens for Electric and other Apparatus," and on "An Astatic Station Voltmeter," both by Prof. W. E. Ayrton, F.R.S., and Mr. T. Mather. A paper on the "Cost of Electrical Energy," by Mr. R. E. Crompton, M.I.C.E., will also be presented.

Institution of Engineers and Shipbuilders.—The seventh general meeting of the North-East Coast Institution of Engineers and Shipbuilders will be held on Wednesday next in the lecture hall of the Subscription Literary Society, Fawcett-street, Sunderland. After the transaction of formal business, Mr. William Bell will reply to the discussion on his paper "On a New System of Construction for Large Vessels of Cellular Type." A discussion will take place on Mr. William Stafford's paper on "Oil-engines," and a paper on "Basis for Classification of Vessels Proportioned to their Strength to Resist Bending and Vibration," by Mr. Arthur R. Liddell, will be read.

Fiume.—According to *L'Elettricista*, an important electric power transmission plant has been erected, and is at work, near Fiume. The water power is obtained from the Burrida, the hydraulic installation having been supplied by the firm of Alberto Riva, of Milan. The total power obtained is 450 h.p., and there are three generators each of 150 h.p., and three electromotors of the same size. Messrs. Brown, Boveri, and Co. have furnished the electrical plant. The dynamos are of the Brown type, and furnish current at 3,000 volts. The power is transmitted to the cotton mills of Messrs. Amman and Co., one of which is at Pordenone, 2½ miles from the generating station, and the other is at Fiume, six miles distant.

Friday's Aurora and the Telegraph Wires.—Mr. W. H. Preece has written to the *Times* as follows: "There was an extremely brilliant display of aurora between 10 and 10.45 p.m. on Friday, the 30th ult. It was accompanied, as usual, by very strong earth currents on all telegraph lines. But at 10.20 p.m., when all the telegraph circuits were idle, a peculiar frizzling and bubbling noise was heard upon a telephone inserted upon a long Irish wire at Llanfairpwll in Anglesey. At 2 a.m. on Saturday, the 31st ult., 'twangs' were heard, as if a stretched wire had been struck. These were followed by a kind of whistling sound. Were these signals from space, or mere disturbances of atmospheric electricity?"

The Kingswood Electric Tramway.—Considerable surprise is being expressed at St. George and Kingswood at the unexpected opposition to the electric tramway, of which notice has been given by two local firms. It is difficult to understand on what ground the opposition is based, seeing that there is an available space of 9ft. 6in. between the kerb and the tramway lines in West-street. The local committees will be at once called together, and the strongest evidence will be obtained in favour of the scheme. The company had given instructions for the preparation of the plans and specifications, and it was intended to proceed with the work as soon as possible after the Royal assent had been obtained to the Bill.

Electrolytic Thermo-electric Cells.—Mr. A. Gockel[1] in the *Ann. Phys. Chem.*, has investigated the E.M.F. of thermo-elements constructed on the following plan:

$$\frac{\text{Hg} \mid \text{solid Hg salt} : \text{salt solution} : \text{solid Hg salt} \mid \text{Hg}}{\text{cold} \qquad\qquad \text{hot}}$$

He finds that, in general, the thermo-electric force for 1deg. difference of temperature increases with dilution of the solution, and that in equivalent dilute solutions of similar salts of an acid it is practically the same. He confirms, in general, Ebeling's observation, that the worst conductors are thermo-electrically the most active, and that some show a maximum thermo-electric force at the concentration of maximum conductivity.

American Institute of Electrical Engineers.—We have received a copy of volume x. of the *Transactions* of this institution, containing reports of the papers and discussions of the past year. Among the papers which are contained in the volume are—"Electrical Recording Meters," by Mr. C. D. Haskins; "The Most Economical Age of Incandescent Lamps," by Mr. Carl Hering; "Impedance," by Mr. A. E. Kennelly; "A New Method for the Control of Electrical Energy," by Mr. D. McF. Moore; and "Practicability of Electric Conduit Railways," by Mr. Albert Stetson. Obituary notices on Dr. Norvin Green, Mr. George B Prescott, jun., and Mr. Anthony Reckenzaun are given. The volume, which comprises over 700 pages, has as a frontispiece a portrait of Mr. Alexander Graham Bell, the seventh president of the institute. The book is published by the institute at 12, West Thirty-first-street, New York.

Tramways Institute of Great Britain and Ireland.—The next council and committee meeting of the Tramways Institute will take place at the Albion Hotel, Manchester, on Thursday next, the 12th inst. The executive committee will assemble at 10 a.m., and the general council at 11 a.m. Gentlemen who intend being present will oblige if they will signify their intention as early as possible to the secretary, Mr. J. G. B. Elliott, 18, Eldon-street, E.C. The following is the agenda: Report of committee on the Board of Trade's regulations for electric traction; discussion on Mr. Schwann's Bill to enable local authorities to work tramways; paper on "Mechanical Tramway Electric Traction," by M. Victor Popp, of Paris; paper on "The Heating of Railway and Tramway Carriages," by Mr. Frank Mellersh; and a paper on "Vereker and Yeats's Car Starter," by Mr. H. L. Furlonge. On the following day visits will be paid to the Manchester tramways and to the Manchester Ship Canal.

Change of Conductivity of a Solution by the Addition of a Non-electrolyte.—Mr. R. J. Holland, in the *Ann. Phys. Chem.*, gives the following account of his general results. The electrical conductivity of a solution of an electrolyte in methylic alcohol diminishes on the addition of a non-conductor, the diminution varying with the nature of the non-electrolyte and with the degree of dilution. The four non-electrolytes benzene, toluene, xylene, and oil turpentine diminish the conductivity in the order given. The diminution varies for each volume per cent. of non-electrolyte added from 1·7 to 2 per cent. of the conductivity of the corresponding normal solution for 0·01-normal solutions; 1·6–1·75 per cent. for 0·001-normal, and 1·4–1·6 per cent. for 0·0005-normal. The temperature coefficients of alcoholic solutions increase with increasing dilution; are only half as great as in the case of aqueous solutions; and are very little affected by the addition of a non-conductor. The conductivity of methylic alcohol solutions up to a concentration of 20 per cent. of non-electrolyte is very exactly represented by Arrhenius's formula. No connection between electrical conductivity and fluid friction was evident.

The Johnstone System of Conduits.—An illustrated pamphlet descriptive of the Johnstone system of conduits has just been issued by the International Electric Subway Company, Limited, of 39, Victoria street, Westminster, S.W. This system of conduits, which was described in this journal some time ago, has been largely adopted in the United States, and particularly in New York, Chicago, and Philadelphia. It has also obtained

Digitized by Google

a firm footing in this country. The Portsmouth Town Council in the latter half of 1893 accepted the company's tender for the whole of the underground mains in connection with the municipal central electric light station. In this case a complete system, extending through upwards of eight miles of streets, including the Johnstone conduit, drawing-in and junction boxes, indiarubber-insulated cables, and an extensive arc lighting circuit, has been put down, in the construction of which several new and specially-designed features have been introduced for the first time. The whole of the work has been carried out very successfully. In addition to this undertaking, the Johnstone conduit has also been laid by the City of London Electric Light Company and by the Keswick Electric Light Company. The pamphlet contains a list of Press opinions and testimonials, and illustrations of the system as carried out at Portsmouth.

Tables and Formulæ for Electric Railway Engineers.—The W. J. Johnston Company, Limited, of 253, Broadway, New York, have forwarded us a copy of a "Reference Book of Tables and Formulas for Electric Street Railway Engineers," by Mr. E. A. Merrill, author of "Electric Lighting Specifications." The object of this book is to meet a practical need by collecting and arranging in a concise, logical order those tables and formulæ which are constantly used by the electric street railway engineer in making estimates, ordering material, on construction work, etc. All superfluous examples and explanations have been excluded, as well as unnecessary extensions of formulæ into tables when such extensions consist only in the simplest arithmetical processes; every element thus stands out in clean-cut, terse form. To facilitate reference without the use of the index, all matter follows a logical order, beginning with the details of the steam plant, and then taking up successively cars and their equipment, overhead work, track work, and miscellaneous tables and formulæ in constant use but only indirectly related to the main division. Considerable care has been taken not only in selecting and checking material compiled directly, but several original tables and formulæ have been added, especially in the sections on calculations. Moreover, many tables and formulæ have been extended and modified so as to meet the conditions imposed by street railway work.

The Reading Electric Supply Company.—Subscriptions to shares are being invited by the Reading Electric Supply Company, Limited, which was incorporated in January, 1892, for the purposes of supplying electricity and electrical energy. The Company has been in negotiation with the Corporation with a view to obtaining the consent of the Corporation to the grant of a provisional order by the Board of Trade giving the Company the right of supplying electricity throughout the whole of the borough, and the terms of this provisional order having been settled between the Company and the Corporation, the Board of Trade has granted the order, which has been confirmed by Act of Parliament. The Company will acquire as a going concern the electric lighting installation and the business which was established in the borough of Reading in 1889 by the Laing, Wharton, and Down Construction Syndicate, Limited, and which has since been carried on by that syndicate under the style of the Reading Electric Light Depôt, together with the freehold land, and the buildings, machinery, plant, etc. The Company is also in negotiation with the Corporation for the acquisition of an alternative site in Mill-lane, which from its central situation and proximity to the River Kennet also offers an advantageous position for the erection of a new and permanent central supply station. The subscription list is now open, and will close on Tuesday, the 17th inst. The capital is £75,000, in 15,000 shares of £5 each, and the present issue comprises £45,000 in 9,000 shares.

The Permeability of Oxygen.—Mr. R. Hennig, in the columns of a German contemporary, gives an account of a new determination of the relative permeability of oxygen and atmospheric air by Toepler's method, the principle of which is as follows: A glass tube of small internal diameter has a slight bend in it, and is placed symmetrically in a magnetic field, the bend being downwards and filled with a short thread of some liquid, the arms on either side being filled with the gases whose permeability is to be compared. If one gas is more permeable than the other, it is attracted with greater force into the magnetic field, and this action is balanced by the force of gravity against which the thread of liquid has to be raised. Any want of uniformity in the field can be detected by filling both limbs with the same gas and observing the deflection, and formulæ are worked out for the difference in permeability, with this correction. Methods of measurement of the field are discussed, and Weber's bifilar method is preferred, owing to the small size of the requisite apparatus and the long range of the values which may be accurately determined. The mean error of the author's observations is about 3½ per cent., and the probable error is 1 per cent. The following table gives the author's result compared with other observers:

Observer.	Temperature. Deg.	Pressure. Atm.	$(\mu_1 - \mu_2) \times 10^6$, reduced to 1 Atm.
Quincke ...	16	1–8	0·097
...	.....	40	0·125
Du Bois ...	15	1	0·093
Curie ...	20	5–20	0·121
Hennig ...	25	1–4	0·096

French Electric Coast Lights.—Some important developments in the matter of electric lights for lighthouses in France have recently been made public, and it has been with a view of obtaining full information respecting *les feux éclairs*, or "lightning lights," that a committee from the Trinity House went over to inspect the lighthouse of La Heve, on the extreme point of the northern bank of the estuary of the Seine, from which a light of the new type had been shown for some months. It was also desired to observe the system of gas-lighted buoys, by means of which the French authorities hope to avoid the necessity of maintaining costly lightships in certain positions. The committee consisted of Captain G. R. Vyvyan, Admiral Sir Leopold M'Clintock, and Captain Slader, elder brethren of the Trinity House, who were accompanied by Mr. Charles A. Kent, the secretary, and Mr. Thomas Matthews, the engineer to the Corporation. At Havre the committee were met by M. Bourdelles, the inspector-general, M. Guiraud, engineer for the Seine district, MM. Ribiére and Vetillart, also engineers of the Lighthouse Department of the Ministry of Public Works, and by them were received with great courtesy. The party visited the lighthouse at La Heve, where the whole of the system was fully explained in detail, the quick flashes of the light being shown to be produced by rapid rotation of the lenses. The committee were afterwards entertained at luncheon, at which the greatest good feeling prevailed, and an earnest desire was expressed on the part of the lighthouse authorities of both countries to co-operate in every possible way in the great work of adding to the safety of sea-voyaging by means of lighthouses and other aids to navigation. The committee subsequently, when crossing the Channel, made some comparisons of the quick flashes of La Heve lights with the slower characteristics of the St. Catherine's electric light, but the results of their observations are not yet made known.

Electric Illumination.—The afternoon lectures at the Royal Institution were resumed on Tuesday, and the first lecture of a course of four on "Electric Illumination" was delivered by Dr. J. A. Fleming, F.R.S. The lecturer began by giving a brief sketch of the progress of electric lighting in the United Kingdom since the Board of Trade enquiry in 1889. There are now about 700,000 incandescence electric lamps in use in London, and about 425,000 in the provinces. The electric supply of the Metropolis is furnished by 13 companies or corporations, and about 60 or 70 towns in the United Kingdom have also a public electric supply. The total length of electric underground mains now laid is about 700 miles. This progress is chiefly the work of the last five years. The lecturer then proceeded to a series of experimental demonstrations intended to illustrate the laws of the propagation of electric currents and the methods by which the energy of a current is converted into heat and light. The light from electric incandescent lamps and arc lamps was next analysed by the prism, and the different qualities of the light emitted by sources at various temperatures examined. It was shown that at the higher temperatures the light was relatively richer in violet rays. Numerous experiments were also shown to illustrate the methods of photometric comparison of lights of different intensities and qualities, and the difficulty of comparison when the lights are at very different temperatures pointed out. For want of a better standard the standard candle is still preserved as a unit of light. The illumination produced by a standard candle at a distance of 1ft. on a white surface is called one candle-foot. This is the least illumination for comfortable reading. Bright moonlight is about one-fiftieth of a candle-foot, whilst diffuse daylight may be 20 to 40 candle-feet. The comparison of the illumination on two surfaces when these differ, not only in brightness or luminosity but in colour, was next discussed, and explanations given of the processes adopted for such photometric comparisons. The remaining lectures of this course will be given on the 10th, 17th, and 24th inst., and will be occupied with the discussion of the methods of electric illumination by arc and incandescence lamps, and descriptions of electric generating stations.

The International Electric Storage, Limited.—As will be seen by our advertisement columns, the International Electric Storage, Limited, has been formed with a capital of £200,000, divided into 40,000 shares of £5 each, of which 9,000 will be allotted to the vendors and patentees. Subscriptions are now invited for the first issue of shares to the extent of £150,000. The Company has been formed to purchase and work the British rights of the invention of Messrs. Theryc and Oblasser for electric accumulators, and it has also acquired the right for 18 months to purchase the patents which have already been obtained in some and applied for in other countries. The directors of the Paris, Lyons, and Mediterranean Railway Company have for over 15 months been making private experiments with the battery. They appointed a commission to report on the battery, and the commission reported in its favour, and have now nearly completed a locomotive to produce nominally 700 h.p., with ability to reach 1,100 h.p. They propose running at a constant speed of about 67½ miles per hour on the level and about 50 miles an hour on gradients. It is expected that the journey from Paris to Nice will be accomplished in 12 hours with this new type of locomotive operated by these accumulators. The Company intends to at once take steps to practically demonstrate the utility of the battery for locomotion on railways, tramway and vehicular traction, the propulsion of boats, for naval and military purposes, traction in mining operations, and for lighting purposes. One of the mail coaches carrying parcels, etc., between London and Chatham, and elsewhere, has been fitted with the Theryc-Oblasser battery, and it has travelled between London and Chatham since March 2, the light giving complete satisfaction. Negotiations with the London Road-Car Company for lighting their vehicles have been nearly completed, and negotiations have been opened with the London General Omnibus Company for a similar purpose. Several of the associated proprietors of omnibuses, as also certain tramway companies, are being arranged with for lighting their vehicles. The price to be paid for the purchase of the British patent, and for the right to purchase the foreign and colonial patents, is £40,000 in cash and 8,000 fully-paid shares. The subscription list was opened yesterday, and will close on or before to-morrow (Saturday) for London and on Monday for the country.

Report on the Hermite System at Worthing.—A report on the results of the trial of M. Hermite's system of treating sewage with electrolysed sea-water has been prepared by Dr. C. Kelly, medical officer of health for the borough. The report contains the results of chemical and bacteriological analyses made respectively by Dr. Dupré, of Westminster, and Dr. Klein, of St. Bartholomew's Hospital. Dr. Kelly says he has not gone into the question of cost, but he points out that besides the annual cost of producing sufficient electrolysed fluid there would be a very great outlay in putting down a fresh set of mains, pipes, and cisterns, so as to convey it to each house. The results of the various tests are set out in detail, and Dr. Kelly concludes: "Since there is no instantaneous decomposition of fæcal matter and no sterilisation of sewage, I am of opinion that the process, as far as the late trials have gone, has therefore failed to produce the results which are claimed for it by its inventor." Concerning this report the Town Council have received a letter, read at an assembly of that body on Tuesday, from Mr. Cooper, of Messrs. Paterson and Cooper, the English agents for M. Hermite. Commenting upon Dr. Kelly's unfavourable report of his experiments at Worthing, Mr. Cooper says Dr. Kelly's conclusions are so utterly opposed to the results found by many of the most eminent experts that he can only think there must be some mistake in taking the samples; at any rate, it appeared to be a very rash proceeding to report upon a process of that sort from a single sample such as appeared to have been submitted to Drs. Dupré and Klein. The letter states: "I am bound to protest against this report. The conclusions arrived at are erroneous, and calculated to give an entirely wrong impression, and I make the statement that when the process is properly investigated the conclusions arrived at will be absolutely opposed to those of Dr. Kelly. There are numerous men of high standing now engaged upon investigating this process, and whose reports we may hope to get shortly. I may quote from the report of Dr. Alain Riton, professor at the Naval Hospital, Brest, and an old student of the Pasteur Institute: 'The experiments that I have made lead me to the conclusion that electrolysed sea-water is a perfect deodorant and an excellent antiseptic, which rapidly destroys the most hardy micro-organisms.' I venture to request that this report of Dr. Kelly's may not be adopted, and that we may be allowed to answer it in detail." Councillor Dr. Goldsmith supported the view that a mistake had been made in taking samples, and said he had been assured by Dr. Ruffer that the solution absolutely killed all microbes. The Council will take no further action until the receipt of the reports promised by Sir Henry Roscoe and Dr. Ruffer.

THE COATBRIDGE CENTRAL ELECTRIC LIGHT STATION.

The Opening of the Works.

By invitation of the directors of the Scottish House-to-House Electricity Company, Limited, a large company assembled on Saturday afternoon at their works in Dundyvan-road, Coatbridge, to witness the opening of the works by Lord Kelvin.. Among those present were the following: Major-General Webber, C.B.; Mr. Timothy Bost, chairman; Mr. Angus Macleod, managing director; Dr. James Colquohoun, LL.D.; Mr. Wm. D. Cairney, C.A.; Mr. John Hannay, Mr. Wm. A. Bryson, M.I.E.E., F.R.S.E.; Prof. Andrew Jamieson, M.I.C.E.; Mr. W. M. Mordey, M.I.E.E.; Mr. W. Geipel, M.I.E.E.; Mr. Francis Teague, M.I.E.E.; Mr. Magnus Maclean, F.R.S.E.; Mr. A. Meikle, M.I.E.E.; Mr. John Kerr, M.I.M.E.; Mr. J. W. Hartley, Sheriff Mair, Mr. John M. Alston, town clerk, Coatbridge; the town clerk of Ayr; Mr. Alex. M'G. Mitchell, Mr. S. Gemmil, town chamberlain, Coatbridge; Bailie Sharp, Bailie Davidson, Bailie Bird, the chairman of the Coatbridge Gas Company; Bailie Wilson, Bailie Chisholm, Bailie Lavell, Bailie Paton, Glasgow; Councillor Angus Campbell, Glasgow; Councillor Don. Hamilton, Glasgow; Councillor Hugh Mayberry, Glasgow; Mr. John Munro, M.I.E.E.; Mr. John Mayer, F.C.S.; Mr. Elsdon Dew, Mr. T. C. Crichton Fulton, Mr. J. I. Hall, Edinburgh; the Rev. Mr. Ireland, the parish minister; and representative ministers of other denominations. The gas generators were first inspected, then one of the gas-engines was started, and Lord Kelvin formally turned on the light at a switchboard in the test-room. Cake and wine were afterwards served, and in reply to the toast of his health, proposed by the chairman of the company (Mr. Timothy Bost), Lord Kelvin said it had been a very great pleasure to him to see what he had seen that day in connection with these works. There had been a great increase in the consumption of electricity, and the case of Coatbridge, he thought, should be an example for the rest of the world to follow. The system which had been adopted there had been tried, and found successful, and in bringing it to Coatbridge he thought the company's judgment had been justified by considering that Coatbridge was a centre which might be available for a supply to other places which had no central station. There were public works not only in Coatbridge, but at distances of two, three, and four miles, which they might look forward to as being supplied with the electric light from the station which they had inaugurated that day. But there was another part of the system which they had seen opened that day, and which, without using too large a word, might be found to have an interest to the whole civilised world. The unique feature of the station was the use of gas-engines. They must not say yet what the results would be, but he thought they had all seen enough to form the most sanguine expectations.

Dr. Colquhoun proposed "The Health of the Provost, Magistrates, and Town Council of Coatbridge," which was acknowledged by Bailie Chisholm. Prof. Jamieson proposed "The Scottish House-to-House Electricity Company," for which Mr. A. M'Leod, managing director, replied. The company afterwards inspected the works.

The System Adopted.

Acting on the advice of their consulting engineer, Mr. Wm. A. Bryson, M.I.E.E., F.R.S.E., the Scottish House-to-House Company decided to depart from the beaten track of central lighting station design, and adopted the novel improvement of utilising the most modern type of gas-engines as the motive power, using carbon-monoxide in lieu of steam, thus avoiding costly foundations, chimney stack, and expensive working staff.

The current is distributed to the various customers on the low-tension alternating system, the mains being fed from transformers fixed in underground chambers placed in convenient parts of the town. The transformers are operated by high-tension feeders, which run from the generating station. The alternators are driven by gas-engines entirely, while the gas is made in producers on the site.

The Station Buildings.

The offices comprise a general office, waiting-room, board-room, engineer's office, testing-room and stores, the floors of which are raised above the level of the works, the engineer's office being so situated that the engineer can command a general supervision of the whole of the engine and dynamo room. Passing through the offices, we come into the engine and dynamo room, which is 53ft. long by 38ft. wide, and while only of sufficient size for the accommodation of the present plant, it is so arranged that the end wall may be easily removed for extensions. The room is lined with whit eglazed bricks. The floor is made of granolithic cement of warm red colour, which gives to it a neat and comfortable appearance. For convenience in operating the machinery there is fixed a very useful and handy five-ton travelling crane by Messrs. Carrick and Ritchie, of Edinburgh. Between the dynamo-room and railway siding is the producer-house, so arranged that fuel may be unloaded direct from the truck on to the charging platform, while the producers are placed in a pit so that the hoppers are at a convenient level; thus the minimum amount of labour is required for passing the coal from the truck into the producer. The buildings have been designed by and erected under the supervision of Mr. Alex. M. E. Mitchell, architect, of Coatbridge.

The Gas-Generating Plant.

There are two gas producers, each capable of generating gas for 120 b.h.p., and they are fitted with Hartley's improved apparatus for removing clinkers. Each producer has an independent set of cooling and cleaning apparatus, consisting of atmospheric cooler, hydraulic box for arresting the passage of dust, etc., coke and sawdust scrubbers, with valve and connection to the gasholder. There are two small steam-boilers for supplying the small quantity of steam required for making the gas, together with steam for starting the gas-engines. The gasholder is 15ft. in diameter by 10ft. deep, and works in a brick tank constructed in the ground adjoining the producer-house.

The Gas-engines.

The gas-engines are of the double-acting type, with an Otto cycle. Each engine has two cylinders placed side by side, and runs at a speed of 180 revolutions per minute, at which speed they are to develop up to 120 i.h.p. A high-speed sensitive governor of the Buss type controls the supply of gas and air, the quantities of which are varied to suit the load down to one-third of full power, below which the governor cuts off a certain number of explosions in the usual way. For starting the engines steam is used. It is admitted by a valve operated by a hand-lever, which the attendant opens and closes, in the same way as a slide-valve is worked by an ordinary eccentric. To ensure steadiness, each pair of engines is fitted with three fly-wheels, so that there is one on either side of each crank. The middle flywheel is grooved for rope driving. For circulating the cooling-water, which is contained in a large tank outside the engine-room, there is used a small centrifugal pump, driven by an alternate-current motor. This motor is operated from the low-tension mains which serve for lighting the station, and is at once an interesting and positive assurance of the suitability of the alternate current for power distribution. A "stand-by" connection has been made with the water company's mains in case of mishap to the pump. The whole of the gas plant and gas-engines have been made by Messrs. Dick, Kerr, and Co., of Kilmarnock, and were put in their places under the superintendence of the manager, Mr. J. W. Hartley.

The Alternators.

The alternators are of the Mordey-Victoria type. Each generates 50 kilowatts at 2,000 volts pressure, the speed being 600 revolutions per minute. The pulleys are 24in. in diameter, with grooves for eight ropes 1in. in diameter. The speed of the ropes is consequently 63ft. per second (43 miles an hour), and the net strain is equivalent to about 100lb. weight per square inch of rope. With a view to ascertaining the most suitable class of rope, one of the alternators is driven by cotton, the others by manilla ropes. The alternators are set in sliding beds, built in flush with the floor, which gives a neat appearance to the machines.

Digitized by Google

Amongst the chief features of the alternators are the stationary armature, any coil of which can be replaced in a few minutes; heavy revolving pole-pieces excited by a single coil concentric with the shaft, thus giving great steadiness of motion and freedom from wear and tear of coils; perfect parallel working at all loads and of all sizes. This has been demonstrated by the parallel working of these alternators at Coatbridge, which are the first alternators which have been so run with gas-engines. This success is doubtless largely due to the steadying momentum of the heavy revolving mass in the poles of the alternators. It is also claimed that the alternators have an unusually high efficiency at all loads. The power of being able to run in parallel has a most important bearing on the all-year-round economy of working, as it is never necessary to run more plant than corresponds with the total load, as is so frequently the case when running alternators on separate circuits, and when the engines would be frequently working under their full power, and consequently with a falling off in efficiency. The output of the three alternators is 150 kilowatts, or 5,000 lamps of 8 c.p. each. Two Victoria dynamos are used as exciters, either of which is capable of exciting all three alternators at one time. They are driven by belts off the shafts of two of the alternators.

The Alternator Switchboards.

Opposite each alternator there is placed an alternator switchboard, on which is provided all the necessary switches and cut-outs, both for the primary as well as for the exciting circuit. The switch for the exciting current is provided with a carbon break. The primary switches are closed and opened by cords, and thus all danger of the operators touching high-tension parts is avoided. On each board is also provided ammeters for both primary and exciting circuits, together with a voltmeter and voltmeter transformer for indicating the primary voltage. There are, in addition, a pair of sockets for connecting the alternators to the synchronising wire. Each alternator board is connected to an omnibus conductor, through which the current passes to the instruments for measuring and recording the total output of the station. For convenience, these main instruments (main ammeter, registering ammeter, and registering voltmeter) are placed on a shelf on the synchroniser board. Under the shelf are placed the synchronisers, while above these are switches for cutting out the main instruments, as well as for closing the synchroniser circuit. On the top of the board are two lamps, which are used in the ordinary way for synchronising. All these boards are so arranged as to make future extension as simple as possible.

The Distributing Mains.

The high-pressure feeders consist of separate stranded conductors, insulated heavily with pure and vulcanised indiarubber, protected with braiding, and drawn into 3in. and 2in. cast-iron pipes. A spare cast-iron pipe has been laid in the ground along the route in order to provide for easy extension, and, in addition, there is laid a 1in. wrought-iron pipe for receiving special arc lighting mains. It will be an easy matter to withdraw any length and substitute a larger cable when occasion requires without breaking up the road. The low-pressure distributing mains consist of stranded cables having seven-eighths or one-tenth square inch section, insulated with vulcanised bitumen and laid in cast-iron troughs, which are then run in solid with bitumen and covered with a cast-iron cover plate. There are at present three transformer sub-stations. They consist of underground chambers about 5ft. square by 6ft. deep, constructed under the pavements at convenient points in the line of the mains. Each chamber is substantially constructed, and is connected with the main drain, so that no water may accumulate, and ample provision has been made for ventilation. The entrance is by a manhole in the pavement about 2ft. square; this is closed by the usual street-box cover. In each chamber there are two 18-kilowatt transformers, which are capable of supplying 1,200 8-c.p. lamps at one time. These are of the Mordey-Victoria type, each being closed in a watertight cast-iron case, and having double-pole primary fuses and switches in the top of the case. The connections to the primary mains are made through cast-iron boxes containing isolating switches, while the secondary mains are connected to omnibus bars, and thence to the transformers through switches and fuses specially designed by the Brush Electrical Engineering Company for this purpose, with Raworth's patent contacts. Either transformer may be switched off the low-tension omnibus bars, leaving the other to supply current, and it will thus be seen that the arrangements permit of complete isolation of any transformer without affecting the supply.

The extension of the distributing plant is easily accomplished without increasing or interfering with the low-tension mains and house-service connections; for whenever the demand exceeds the capacity of the main, it is merely necessary to construct an additional transformer-chamber, which has at once the effect of doubling the capacity of the low-tension mains at that point, while the high-tension mains already have spare carrying capacity and provision for drawing in another high-tension feeder. Thus there is provided every facility for extension without again breaking up the streets, so far as concerns those thoroughfares in which the mains are already laid.

The supervision of the work has been in the able hands of the company's resident engineer, Mr. Francis Teague, M.I.E.E., while the construction of the electrical portion of the work has been carried out under the supervision of Mr. W. Geipel, M.I.E.E., the capable superintending engineer of the Brush Electrical Engineering Company.

THE BEST RESISTANCE FOR THE RECEIVING INSTRUMENT ON A LEAKY TELEGRAPH LINE.*

BY PROF. W. E. AYRTON, F.R.S., PAST-PRESIDENT, AND C. S. WHITEHEAD, M.A.

1. If there be a single earth fault at any one point of an otherwise good telegraph line, P Q, Fig. 1, it is easy to

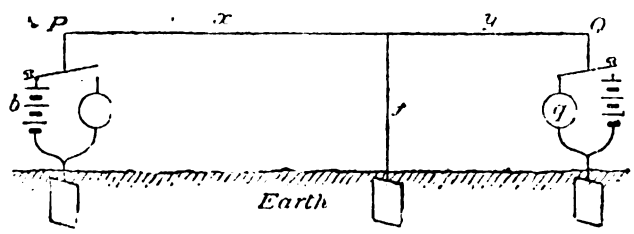

Fig. 1.

prove that the best resistance to give to the receiving instrument at either end of the line is equal to the apparent resistance of the line tested from that end when put to earth at the other end through a resistance equal to that of the signalling battery at that end. For example, if we desire to know what shall be the value of q, the resistance of the receiving instrument at the Q end, the line must be tested from the Q end, Fig. 2, when put to earth at the P end through a resistance, b, equal to that of the signalling battery usually employed at that end.

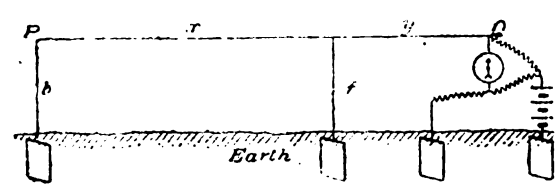

Fig. 2.

For if E be the E.M.F. of the signalling battery at the P end, f the resistance of the single earth fault, and x and y the resistances of the two portions of the line, the current, A, that flows through the receiving instrument at Q, Fig. 1, equals

$$\frac{f}{f+y+q} \times \frac{E}{b+x+\frac{f(y+q)}{f+y+q}}.$$

And the magnetic effect produced by an electromagnet of given size, shape, and construction is proportional to the product of the current into the square root of the resistance

* Paper read before the Institution of Electrical Engineers.

Digitized by Google

of the wire with which the coil is wound. Therefore it follows that the magnetic effect of the receiving instrument at Q is proportional to A $\sqrt{q}$—that is, to

$$\frac{f\,E\sqrt{q}}{(f+y+q)(b+x)+f(y+q)};$$

and this has a maximum when

$$q=y+\frac{f(x+b)}{f+x+b},$$

that is, when q is equal to the apparent resistance of the line tested from the Q end and put to earth at the P end through a resistance, b.

2. During the course of some lectures at the Guilds Central Technical College last year on faults on telegraph lines, the question arose whether the above result was universally true for a distributed leak all along the line, or only for a single earth fault; and if this solution were not generally true, then what was the best resistance to give to the receiving instrument at the end of a telegraph line the leakage along which followed any law. The following is the complete solution of this question:

Let x be the resistance of the line up to any point measured from the sending or signalling end, P, and let $F(x)$ be the insulation resistance of a length of wire at that point having one ohm conductor resistance. When a signal is sent, let V be the P.D. set up between the line and the earth at the sending end, Fig. 3, and v the

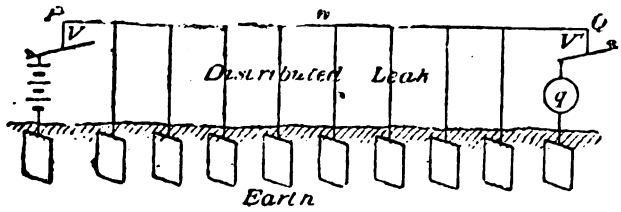

FIG. 3.

potential of the line at any point x; then v is given by the equation,

$$\frac{d^2v}{dx^2}=\frac{v}{F(x)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If $F(x)$ be some simple known function of x, it may be possible to integrate this equation, and in that case we may proceed by performing the integration. For example, if $F(x)$ be a constant, t—that is, if the line be uniformly leaky—then, integrating, and introducing the terminal conditions, it may be shown that

$$v=V\frac{(\sqrt{t}-q)\epsilon^{\frac{x-w}{\sqrt{t}}}-(\sqrt{t}+q)\epsilon^{\frac{w-x}{\sqrt{t}}}}{(\sqrt{t}-q)\epsilon^{-\frac{w}{\sqrt{t}}}-(\sqrt{t}+q)\epsilon^{\frac{w}{\sqrt{t}}}} \quad . \quad (2)$$

where w is the true wire resistance of the whole line, and q is the resistance of the receiving instrument at the far end, Q.

Hence the current passing through this receiving instrument, which is $-\frac{dv}{dx}$ when x equals w, has the value,

$$\frac{2V}{(\sqrt{t}+q)\epsilon^{\frac{w}{\sqrt{t}}}-(\sqrt{t}-q)\epsilon^{-\frac{w}{\sqrt{t}}}};$$

and the magnetic effect, M, is proportional to this expression multiplied into $\sqrt{q}$. From this it may be shown that M is a maximum when

$$q=\sqrt{t}\,\frac{\epsilon^{\frac{w}{\sqrt{t}}}-\epsilon^{-\frac{w}{\sqrt{t}}}}{\epsilon^{\frac{w}{\sqrt{t}}}+\epsilon^{-\frac{w}{\sqrt{t}}}} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Now, if one end of the line be put direct to earth, we must make q equal to nought in equation (2). Under these circumstances the current $-\frac{dv}{dx}$ at any point x equals

$$\frac{V}{\sqrt{t}}\,\frac{\epsilon^{\frac{w-x}{\sqrt{t}}}+\epsilon^{\frac{x-w}{\sqrt{t}}}}{\epsilon^{\frac{w}{\sqrt{t}}}-\epsilon^{-\frac{w}{\sqrt{t}}}} \quad . \quad . \quad . \quad . \quad (4)$$

and therefore the current entering the other end of the line, where the potential is V_1, say, has the value,

$$\frac{V_1}{\sqrt{t}}\,\frac{\epsilon^{\frac{w}{\sqrt{t}}}+\epsilon^{-\frac{w}{\sqrt{t}}}}{\epsilon^{\frac{w}{\sqrt{t}}}-\epsilon^{-\frac{w}{\sqrt{t}}}} \quad . \quad . \quad . \quad (5)$$

If V_1 then be the potential at the point Q when the line is tested from the Q end and put direct to earth at the P end, Fig. 4, the apparent resistance of the line will be V_1 divided by the expression (5), and therefore equals

$$\sqrt{t}\,\frac{\epsilon^{\frac{w}{\sqrt{t}}}-\epsilon^{-\frac{w}{\sqrt{t}}}}{\epsilon^{\frac{w}{\sqrt{t}}}+\epsilon^{-\frac{w}{\sqrt{t}}}};$$

but this is exactly the same as the value found in (3) for q, which made M a maximum. Hence the receiving instrument ought to have a resistance equal to the apparent resistance of the line when tested at the receiving end and put direct to earth at the sending end.

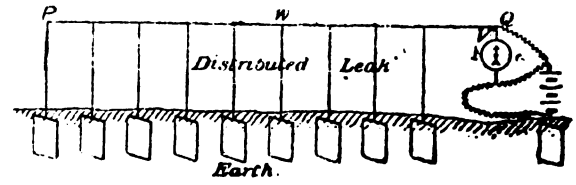

FIG. 4.

The resistance of the signalling battery does not in this case appear in the best value to give to q, but that arises from the fact that, whereas when we were dealing with a single earth fault we assumed that the signalling battery had a fixed E.M.F. and a fixed resistance, b, here we have assumed that V, the potential of the sending end of the line, was kept constant. Now this is the same thing as supposing that the signalling battery of fixed E.M.F. has an extremely low internal resistance. The two results are therefore the same.

3. Returning now to the general differential equation,

$$\frac{d^2v}{dx^2}=\frac{v}{F(x)} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

we see that, if the distributed leak may follow any law, $F(x)$ may be any function of x. The equation, therefore, cannot be integrated, and we must deal with the problem of determining the best resistance to give to the receiving instrument at the end of the leaky telegraph line without actually integrating equation (1), and without expressing in an explicit form the value of the current that passes through the receiving instrument.

To ascertain the general form of the solution of the above differential equation, whatever function $F(x)$ may be, let one solution be

$$v=\phi(x);$$

then

$$\frac{d^2\phi(x)}{dx^2}=\frac{\phi(x)}{F(x)} \quad . \quad . \quad . \quad . \quad (6)$$

Eliminating $F(x)$ from equations (1) and (6), we have

$$v\frac{d^2\phi(x)}{dx^2}-\phi(x)\frac{d^2v}{dx^2}=0;$$

$$\therefore \frac{d}{dx}\left\{v\frac{d\phi(x)}{dx}-\phi(x)\frac{dv}{dx}\right\}=0.$$

Digitized by Google

and $v\frac{d\phi(x)}{dx} - \phi(x)\frac{dv}{dx} =$ some constant, say b;

$$\therefore \frac{d}{dx}\left\{\frac{v}{\phi(x)}\right\} = \frac{b}{\{\phi(x)\}^2},$$

or

$$\frac{v}{\phi(x)} = a + b\int\frac{dx}{\{\phi(x)\}^2};$$

$$\therefore v = a\phi(x) + b\psi(x) \quad . \quad (7)$$

is the general form of the solution of the original differential equation, the values of the constants, a and b, depending on the terminal conditions. In fact, as the differential equation No. 6 is linear, it is almost obvious, without any proof, that the general solution of this equation must be of the form given in (7).

In our particular case (Fig. 3) the terminal conditions are,

when $x = 0, \quad v = V,$

and when $x = w, \quad v = V';$

also, when x equals w, the current, A, flowing through the receiving instrument at the Q end of the line, or $-\frac{dv}{dx}$, equals $\frac{V'}{q}$.

$$\therefore V = a\phi(0) + b\psi(0) \quad . \quad . \quad . \quad (8)$$

and

$$V' = a\phi(w) + b\psi(w) \quad . \quad . \quad . \quad (9)$$

$$\therefore \frac{V'}{q} = -a\phi'(w) - b\psi'(w) \quad . \quad . \quad (10)$$

if we write $\phi'(w)$ and $\psi'(w)$ for $\frac{d\phi(w)}{dx}$ and $\frac{d\psi(w)}{dx}$ in the usual way.

Hence, eliminating V' from equations (9) and (10),

$$a\{\phi(w) + q\phi'(w)\} + b\{\psi(w) + q\psi'(w)\} = 0 \quad (11)$$

Eliminating b from equations (8) and (11),

$$a\{\phi(0)\psi(w) + q\phi(0)\psi'(w) - \psi(0)\phi(w) - q\psi(0)\phi'(w)\} = V\{\psi(w) + q\psi'(w)\} \quad . \quad . \quad . \quad (12)$$

also eliminating a from the same two equations,

$$b\{\psi(0)\phi(w) + q\psi(0)\phi'(w) - \phi(0)\psi(w) - q\phi(0)\psi'(w)\} = V\{\phi(w) + q\phi'(w)\} \quad . \quad . \quad . \quad (13)$$

therefore, substituting in equation (7) the values of a and b given by equations (12) and (13), we have

$$v = V\frac{\{\psi(w) + q\psi'(w)\}\phi(x) - \{\phi(w) + q\phi'(w)\}\psi(x)}{\phi(0)\psi(w) + q\phi(0)\psi'(w) - \psi(0)\phi(w) - q\psi(0)\phi'(w)}.$$

Now A, the current flowing through the receiving instrument at the Q end of the line, is $-\frac{dv}{dx}$, where x is made equal to w; therefore

$$A = V\frac{\psi(w)\phi'(w) - \phi(w)\psi'(w)}{\phi(0)\psi(w) + q\phi(0)\psi'(w) - \psi(0)\phi(w) - q\psi(0)\phi'(w)},$$

and the magnetic effect is proportional to A $\sqrt{q}$, and will, therefore be a maximum when

$$q = \frac{\phi(0)\psi(w) - \psi(0)\phi(w)}{\phi(0)\psi'(w) - \psi(0)\phi'(w)} \quad . \quad . \quad (14)$$

Next, let the line be put direct to earth at the P end, and the apparent resistance of the line, with its non-uniformly distributed leak, tested from the Q end, Fig. 4: then, if x be still reckoned from the P end of the line, the terminal conditions for determining the constants in the general solution,

$$v = a\phi(x) + b\psi(x) \quad . \quad . \quad . \quad . \quad (7)$$

are, when $x = 0, \quad v = 0,$

$$x = w, \quad v = V_1;$$

$$\therefore v = V_1\frac{\phi(0)\psi(x) - \psi(0)\phi(x)}{\phi(0)\psi(w) - \psi(0)\phi(w)};$$

and since the apparent resistance of the line tested from the Q end equals V_1 divided by $\frac{dv}{dx}$, when x is made equal to w, this apparent resistance will be—

$$\frac{\phi(0)\psi(w) - \psi(0)\phi(w)}{\phi(0)\psi'(w) - \psi(0)\phi'(w)};$$

but this is exactly the same as the value of q given in equation (14), that made the magnetic effect a maximum. Hence we may conclude that, whatever be the nature of a leak on a telegraph line, whether the leak be a single one, or be distributed along the line according to any law of distribution, the same rule holds true for the best resistance to give the receiving instrument—viz., the receiving instrument at either end should have a resistance equal to the apparent resistance of the line when tested from that end and put direct to earth at the other end.

In what precedes it is assumed that the resistance of a coil of wire occupying a given form and volume is proportional to the square of the number of convolutions. This is absolutely true either when the thickness of the insulating covering is negligible compared with the thickness of the copper, or when the ratio of thickness of the insulating coating to the diameter of the copper is constant for each gauge of wire employed. In a paper on galvanometers* published in the *Proceedings* of the Physical Society, examples are given of similar coils of silk-covered wire of very different resistances where this proportionality of resistance to the square of the number of windings holds very well. In some other cases, however, as will be seen by referring to that paper, the resistance is more nearly proportional to the number of windings raised to the power five halves.

It is therefore worth while considering how the rule given above for the test resistance for the receiving instrument would be varied if the coil of the receiving instrument were wound with such insulated covered wire that M, the magnetic effect, instead of being proportional to A $\sqrt{q}$, were proportional to A q^n. In that case it may be shown that M will be a maximum when

$$q = \frac{n}{1-n}\frac{\phi(0)\psi(w) - \psi(0)\phi(w)}{\phi(0)\psi'(w) - \psi(0)\phi'(w)};$$

and this is $\frac{n}{1-n}$ times the apparent resistance of the line when tested from the receiving end and put direct to earth at the signalling end.

ELECTRIC STATION ECONOMICS.†

BY PROF. D. C. JACKSON.

Small economies in electric station management and operation are things which have a peculiar faculty of swelling up to big totals, a fact of which wideawake managers with eyes to profitable running have had ample opportunity to satisfy themselves. One of the items entering largely into the question of economical operation is the equipment of station instruments. The term station instruments may be made to cover a variety of tools and indicating devices, from the coal-shovel to the main fuse block. The essential electrical instruments are such as will enable station men to handle dynamos and look after their regulation with the greatest precision, but with the expenditure of the least labour and with the least possibility of accident. With the usual construction, the electrical instruments are mounted collectively on a switchboard, but seldom in the best manner. Remember that accidents may involve, first, the operator; second, the plant; third, any branch of the plant.

Safety of Plant.

In discussing the subject recently before the North-Western Electrical Association, the author took occasion to point out that while safety for careful operators is usually provided, the safety of the plant itself is seldom considered. Fires, for example, have been far too frequent and disastrous in their occurrence. A great many of the fires in electric stations start at the switchboard. These can be made almost absolutely safe, and, with proper construction, switchboard fires should be almost unknown. How many stations have properly constructed switchboards? And how many stations pay a fairly low rate of insurance? A saving of 25 cent. on insurance rates will pay for considerable improvement in the switchboard. By making

* "Galvanometers," by Prof. Ayrton, T. Mather, and W. E. Sumpner, D.Sc., *Phil. Mag.*, July, 1890, page 86.

† From *Cassier's Magazine*.

Digitized by Google

the improvements and insisting upon intelligent inspection by the insurance companies, the improved rates can be secured. At the same time a guarantee against fire is obtained.

This is better than insurance, for, however well the insurance companies may treat one after a fire, they will never repay all the losses incurred. Build switchboards of non-combustible material. Marble is not very expensive and is better than slate. If combustible material is used for the board, never make it solid, but arrange it simply as a skeleton upon which the instruments may be secured. Set the switchboard at least 2ft. (3ft. is better) from the wall, and have all the wiring done in the best possible manner and in plain sight. Under no circumstances close the ends of the space back of the board, making it into a sort of rubbish closet. Keep the space all around the board light and clean. Nothing will guarantee neat, safe wiring and safe storage of material except the entire absence from the station of dark corners and closets. There are, by the way, few station hands who will wire a switchboard in a neat and safe manner without excessive expense unless they are carefully directed.

The Switchboard.

The switchboard should be located conveniently and the instruments conveniently placed thereon. The dynamo instruments should be bunched together, and the different devices belonging to each individual dynamo circuit should be placed in vertical rows. This avoids the probability of the accidents to machinery which are bound to occur when the instruments are irregularly distributed. System at the switchboard is just as important to economy as is system in the accounting methods. Pressure indicators, cutting in galvanometers, ground detectors, and other instruments which are common to all the dynamos should be placed where they are easily seen by a man at the dynamo regulators. Devices placed in the feeder circuits may be placed either above or at one side of the dynamo instruments. In any case, the arrangement should be such that extensions may be readily made.

The number of instruments on the dynamo and feeder circuits should never be multiplied unnecessarily. Their type and number in any case depends upon the type of the apparatus, and the purpose for which it is used. Thus arc light plants require an arrangement which differs completely from that which is required in alternating incandescent stations, and the latter differs from that required in stations supplying a continuous-current constant-pressure distribution. If arc light dynamos with separate regulators or controllers are used, these should be solidly mounted near the dynamos to which they belong. In each case the maximum of safety and convenience should be sought in the choice and arrangement of the instruments. The arrangement of the standard panel switchboards of two or three prominent manufacturing companies may be followed with profit. Where two or more classes of machinery are used, the different types of dynamos should be set together and the switchboards should be distinct, but side by side.

The Steam Question.

Let us drop the electrical question now and go over to the steam side. We will start with the coal-bin and simply touch upon the instruments or tools not generally used, but which can usually be advantageously added to the equipment—that is, which are likely to add to the dividend-paying capacity of the station. The first instrument on this list is a platform scale for weighing in the coal. Daily records of coal consumed should be carefully kept and compared with records of the electrical output, day by day, week by week, and month by month. Complete daily records enable a station manager to readily determine whether he is getting the results with the least expense. The coal records also enable a direct comparison of the economy of the different grades of coal. Many station managers give too little attention to this matter, simply purchasing the grade of coal which happens to have the lowest price per ton. This is frequently all right, but sometimes it is not economical.

The coal-shovel is an instrument which requires a great deal of careful supervision. The coal records and automatic records of steam pressure serve this purpose. An automatic steam-pressure recorder is not an expensive instrument. If one is properly installed and its indications are acted upon by the manager, it will soon save its cost. There are various automatic recorders. A first-rate one is the Bristol. The Edison, which is more expensive, has some advantages which are, however, of little moment in a small plant. Those who have operated stations both where pressure recorders are and are not used, will doubtless be ready to bear witness to their advantages. Thermometers in the feed-water pipe and in the steam-pipe are not essential to the operation of a station, but they are certainly advantageous. A throttling calorimeter made of ordinary fittings is also serviceable. The use of the thermometers and calorimeter may look like kid-glove engineering, but if one is anxious to get the best result from a steam plant for the least cost, they should be employed. They are not kid-glove affairs, but good common-sense appliances. Steam-gauges on the boilers (good reliable ones) all will agree are essential, but it is not usual to put one in the steam-pipe near the engine. It is a good idea, however.

I am acquainted with a plant of considerable size which operates 24 hours a day. During daylight the load on the plant is small, and in such cases it is the impulse of the average fireman and engineman to throttle the steam by partially closing the boiler valve. In the station I speak of the reduction in the pressure is 20lb. Let us see the result. In first bringing the boiler pressure up to 100lb. above the atmosphere a certain amount of heat is furnished to the steam from the fuel. Where the pressure is reduced by throttling, the steam is cooled to a lower temperature and some of the heat contained in the high-pressure steam is lost. This loss means an equal decrease in the power of the steam, and, therefore, the coal which was used in raising the pressure from the low figure to the high one is simply thrown away. When it is necessary on account of light day loads, it is much more economical to lower the boiler pressure to a satisfactory figure. In the station referred to the loss in fuel on account of throttling was from 5 to 10 per cent. Five to 10 per cent. of the fuel used on day load makes a considerable item in the period of a year, which will pay for the recording boiler gauge and a gauge in the engine pipe, besides adding a sum to the dividend account. It is true that the gauge in the engine pipe does not remove the fireman's impulse to reduce pressure by throttling, but if his work is constantly under inspection the impulse is much less likely to be irresistible. In this connection let me remark regarding the usual practice of cutting off the condenser at times of light load when condensing engines are used. Under such circumstances fuel is saved by keeping the condensers running, but reducing the boiler pressure to hold the engine cut-off at an economical point.

The Engine Indicator.

Another instrument of much value is the engine indicator. This is particularly useful in determining whether the engines are working at their most economical cut-off, and whether the valves are properly set. A great many engineers tinker with their engine valves, and rely upon their eye and ear to set them properly. This is generally poor economy, and the indicators should be brought into requisition. If cards are taken at fixed intervals and filed for reference, they may be made a decided aid in the effort to keep everything at the most economical point. In the valve setting alone, if the indicator can point out the way of saving a very small per cent. of fuel, it will quickly pay for itself in this country of expensive coal. The horse-power calculated from the diagrams, compared with water and fuel records, and again with electrical records, give all the elements necessary for determining at any time whether the plant is doing its duty satisfactorily.

I have spoken particularly of instruments that are frequently not used in the stations, but which can be made of much valuable assistance in reducing expenses. These are not varnished, theoretical ideas, but hard, common-sense, dividend-earning suggestions. They can be put into service without increasing the operating costs in any way, and the instruments will ordinarily quickly pay for themselves.

THE GENOA ELECTRIC TRAMWAY.

During the course of last year an electric tramway on the overhead trolley system was constructed and set in operation at Genoa. This line has been described by M. L. Respighi in the columns of an Italian contemporary, *L'Elettricista*. The ample precautions which have been taken to ensure a safe and efficient service have prevented any disturbances being set up in the telephone circuits, which are carried parallel with the tramway. The feeders are carried on brackets attached to the walls of the houses, and the transverse wires supporting the trolley wire are arranged at a height of 23ft. from the ground.

The tramway is worked under a concession granted by the municipality of Genoa to the Electric and Cable Railway Company of Kerns, Switzerland. The concession authorises a line from the place Corvetto to the place Manin, through the rue Assarotti, which is already in operation, and which has to be extended so as to reach the generating station; and a line from the place Corvetto, through the rue San Filippa and San Giacomo, la rue Serra and la place Brignole. Considerable difficulties were encountered in the carrying out of the first-mentioned line. The rue Assarotti extends in a straight line, with an incline varying between 6, 7, and 8 per cent. Each car with a load of 25 passengers had to travel at 7½ miles an hour, and to stop at several points on the route both in making ascents and descents. It was considered to be impossible for the line to be worked other than by electric power.

The capacity of the station is 450 h.p., with three boilers, three engines, and three dynamos, one of each of which is kept as reserve. At present only two boilers, one engine, and one dynamo are in use, this plant being sufficient to operate the line of tramway now worked. The engine, which was made by Messrs. Tosi, is of the compound type. The boilers are of the Cornovaglia type, working at 157lb. pressure, and fed by means of two duplex steam-pumps. The dynamos are of the Siemens and Halske compound type, giving at 420 revolutions a current of 200 amperes at 525 volts.

The main cable is carried on insulators fixed to wooden posts as far as the place Manin, where the head of the line of tramways is situated; it is 1,250 metres in length, and is supported on posts at intervals of 40 metres. This cable contains eight wires of 7·5mm. diameter. At the place Manin four of these wires are united and soldered to the rails, which are of the Phénix type; the other four wires serve as feeders to the service or trolley wire. One single wire really suffices for the working of the line in operation, and two other wires cross the town and terminate at the end of the line in the place Brignole, so as to furnish current to the tramway in the rue Serra. Another feed wire will be carried to operate the motor of the cable line to be built.

Great precautions have been taken in constructing the tramway so as to ensure perfect insulation. With regard to the line, the brackets, which are of iron, are fixed to the wall by means of a circular plate and four bolts. The vertical rods which support the insulators are fixed to and insulated from the brackets. The transverse wires carrying the service or trolley wire are of galvanised iron, arranged at intervals of from 40 metres to 50 metres. The service wire is of phosphor bronze, 7·5mm. diameter, and instead of using a trolley wheel, a wire is used to collect the current; this contact wire is a simple iron wire, 8mm. diameter, passing over the service wire, and is said to answer its purpose exceedingly well.

The cars are lighted by means of five 16-c.p. incandescent lamps energised from the line. Each car is equipped with two 18-h.p. motors of the Siemens and Halske type. The gearing consists of an endless screw connected to the armature shaft, and engaging with a toothed wheel carried on the car axle.

There are at present four electric cars in operation. The electrical equipment was furnished by Messrs. Siemens and Halske, and the tramway was carried out under the superintendence of Mr. W. Reichel, of that firm. It is intended to place 24 cars on the other lines now in course of construction, and of which six will shortly be placed on the Corvetto-Stagliano route.

COST OF PRODUCING ELECTRICITY.

A committee on data is maintained by the National Electric Light Association, and during the past year the committee have endeavoured to collect information relative to the cost of running electric supply stations in terms of coal consumed per watt-hour.

The committee was requested to furnish the convention with the facts regarding the amount of coal used in actual practice to produce a given quantity of electricity. The information was obtained by correspondence, and furnished the committee in amperes, volts, and hours on each circuit, and the amount of coal used covering this period, including that used for banking fires, etc. The aggregate electrical output for 24 hours was then calculated and compared with the total amount of fuel used, giving the watt-hours per pound of coal. All improbable and apparently erroneous reports were discarded, and the tabulated statement submitted in the committee's report comprises intelligent replies from a large number of the electric stations, including many of the leading corporations. The great saving in operating in large units and running continuously is plainly evident from the report which shows 208 watt-hours per pound of hard screenings where about 8,000,000 watts were generated, running full 24 hours, as against the report which claims only 30 watt-hours per pound of soft coal, the total output being less than 60,000 watts, and the service being furnished only seven hours. The best reports do not compare favourably with the results secured in generating power for manufacturing purposes.

In order to facilitate this comparison, the committee prepared a table based on 90 per cent. mechanical efficiency in the engine, and the same efficiency in the dynamo. Then

$$\frac{746 \times \cdot 90 \times \cdot 90}{\text{coal per hour}} = \text{watt-hours per pound of coal.}$$

And

Coal per hour per i.h.p.				Watt-hours per pound of coal.
1·5lb.	should	produce		402·84
2	,,	,,	,,	302·13
3	,,	,,	,,	201·42
4	,,	,,	,,	151 06
5	,,	,,	,,	120·85
6	,,	,,	,,	100·71
7	,,	,,	,,	86·32
8	,,	,,	,,	75·53
9	,,	,,	,,	67·14
10	,,	,,	,,	60·43
11	,,	,,	,,	54·93
12	,,	,,	,,	50·35
15	,,	,,	,,	40·28
18	,,	,,	,,	33·57
20	,,	,,	,,	30·22

From this estimate of engine and dynamo loss, 1½lb. of coal should produce 402·24 watt-hours. The committee had a report from the Chelsea Jute Mills, of Brooklyn, N.Y., covering a period of six days, where an average of 653·3 i.h.p. was developed from a coal consumption of 1·482lb. per indicated horse-power per hour, the load varying from 495·21 h.p. to 764·96 h.p. This equipment consists of Corliss compound condensing engines and vertical tubular boilers. The plant was in operation 10 hours each day. The figures given cover the whole amount of fuel used, including banking, etc. The fuel was George's Creek bituminous coal.

If the committee's percentage of efficiency is correct, and if a fairly uniform electrical output could be obtained, this plant, the *Electrical Review* of New York says, ought to produce over 400 watt-hours, or double that of the most favourable report given in the committee's tabulated statement, more than double that of the next best report, thirteen times the efficiency of the plant making the lowest report, and between four and five times the average efficiency of the whole report. The report shows an average of 91·7 watt-hours per pound of coal—a very low average indeed—thus requiring the consumption of nearly 7lb. of coal per indicated horse-power.

STORAGE BATTERIES IN CENTRAL STATIONS.

At the recent meeting of the National Electric Light Association at Washington, the question of using storage batteries in central electric light stations was brought forward for general discussion, no paper on the subject being presented. The following is a report of the discussion.

Mr. BRACKEN, of New York, said: As one who has been associated with the storage battery interests in this country from its inception, I have been asked by a number of storage battery representatives to open this discussion with a few preliminary remarks. I understand to-day the subject will be confined to their use in central stations. I am afraid that most of the storage battery men will approach this subject with some degree of diffidence by reasonable scepticism that exists in the minds of a very large percentage of the central-station men about storage batteries. Peace now reigns over the storage battery interests in this country. The companies have come in under one flag, and are united for a common interest, so that you may purchase a storage battery to-day with the confidence that that you are not going to be annoyed by threats of suits for infringement. You not only have the advantage of peace, but you also have the advantage of the experience which has been gained both in this country and in Europe by these companies. We had the representatives of several foreign companies here this summer, and we got a great deal of useful information from them. It is also natural that you should desire a certain guarantee as to the cost of maintenance and efficiency of the batteries. As to the nature of the guarantees, any persons desiring to instal a storage battery plant in his station can readily satisfy himself as to the life of the plants. He can then guide himself by getting proper guarantees as to the cost of maintenance. I do not think there is any company asking a larger percentage than 10 per cent. for the cost of maintaining the battery. I have no doubt that experience will prove the cost of maintenance to be less.

Mr. P. G. SALOM observed: The question of the advisability of the use of storage batteries at the present time in central-station plants is purely a commercial one. Will it pay? All of you agree that storage batteries are a desirable adjunct to have in central-station practice, but you are deterred for two reasons. First, you do not know positively that the investment will show a decrease in operating expenses; and, second, you are still more uncertain as to the cost of maintenance of the plant after you have made the investment. Now, in order to answer these questions intelligently, the first requisite in this or any other quantitative determination is to have a unit or standard. This unit or standard is the cost of producing a given quantity of electrical energy under certain normal and fixed conditions. In other words, given a standard engine and dynamo of the average size used in central stations, what is the cost per kilowatt-hour or ampere-hour? Having determined this cost, based on a given price for coal and labour, each central-station operator can determine at the end of the year how closely he approximates this ideal cost by dividing his total output into his total operating expenses, and, further, by keeping careful records he can also determine what factor or factors are operating to prevent his attaining the ideal results. For example, if by reason of his geographical location his coal costs him twice as much as the price assumed in the original estimate, his operating expenses will be increased proportionally, and if they exceed this additional amount he must look to other factors to explain the increase. Having determined all these factors for his own individual case, it becomes a simple question of arithmetic for him to determine whether with an additional investment for a battery with a given output and efficiency and at a given cost for maintenance, he can advantageously add to his plant a storage battery. No hard and fast rule can be adopted. No two central stations are alike, either in equipment or output, and, therefore, the best size of battery equipment or proper proportion of battery to other units may never be exactly the same in any two cases. Now, the second question may be briefly answered by the statement that we are now prepared to give responsible guarantee that the maintenance of the battery shall not exceed a certain reasonable cost per annum, and which, of course, has been duly considered in estimating the additional cost and savings of a storage battery plant.

Mr. J. APPLETON said: The Germantown Electric Light Company had the distinction of being the first electric lighting company to use a storage battery equipment of American manufacture and design. The company had a day load of incandescent lamps and motors on the three-wire system which was very unprofitable, and about 15 months ago they decided to try the use of a storage battery to see if the day load could not be made profitable instead of a dead loss. A small battery was put in sufficient to carry the day load; its capacity was 800 ampere-hours with a normal rate of discharge of 80 amperes. The machinery was then shut down from daylight till dusk, the battery taking care of the day load. This being an experiment to ascertain the true facts about the working and value of a storage battery for central-station purpose, very careful figures were kept, and the result of the first year's working was eminently successful and resulted in a large saving. According to Mr. Allen, the superintendent of the station, the saving on the one year's running in labour, coal, water, oil, waste, etc., not counting the decreased depreciation of machinery due to shutting down from daylight to dusk, was 2,500dol. Besides this there was a great advantage in being able to overhaul and examine all machinery in the daytime while everything was shut down. This being so satisfactory, and the behaviour of the battery being equally good, the Germantown company decided to put in a battery of 2½ times this capacity, which would enable it to increase the day load and consequently increase the savings, as the cost of charging a large battery is only the extra fuel required. This larger battery was installed at the beginning of this year, and is the one which I will now describe. The battery consists of 120 cells of the chloride type G, 11 plates in each, arranged 60 on each side of the three-wire system. The capacity of the cell is 1,000 ampere-hours, or 2,000 hours with both sides. The normal rate of discharge is 200 amperes, maximum 400, and this can safely be increased in case of sudden demand or emergency. The plates are protected by the improved asbestos insulation, and are contained in lead-lined wood tanks. An asphalte floor, well drained, is provided, so that there is no trouble in handling the acid. One special feature of these cells is the size of the plates, 15in. square. Anyone who has had experience with storage battery will appreciate this point, and will readily understand how much less trouble and expense there is in the maintenance, when only 11 plates are required to give 1,000 ampere-hours' capacity instead of about 80 plates. Plates of the chloride type can be constructed larger than this without any difficulty, and give equally good results. This battery plant has been designed to meet all the requirements of the three-wire system, and to give the greatest possible flexibility. The ordinary course of working in the Germantown station is as follows: The machinery is shut down at daylight and the battery carries the whole of the day load till dusk, when the dynamos are started again. The battery is then switched out during the hours of heavy load, and started in again for charging when the load decreases. By this means the general plant is working at an efficient load during all the hours it is running, and the extra fuel for charging the battery is hardly noticeable. The daily routine is very simple; the discharge of the battery is noted by hourly readings, and at the end of the day the total discharge is ascertained. A charge of about 10 per cent. in excess of the discharge is put in, and this is found to be sufficient. In some cases even less charge than this will bring the cells up to the proper E.M.F. Just before the end of the charge readings are taken in some of the cells with the hydrometer and voltmeter, and the condition of a cell can be accurately ascertained. The maintenance of a storage battery is the point which frightens most engineers. In the old days 46, 50, and 60 per cent. efficiency was the average result, and this, I believe, is the chief reason of the slow adoption of the batteries. Until recently, sufficient attention was not paid to designing the cells for the work they had to do. Engines and dynamos

Digitized by Google

are designed and installed according to the nature of the work they have to perform, and this must be done with batteries. Given a properly designed and installed battery, such as the one I have described, the maintenance and depreciation will not exceed that of the other portion of the central-station plant. A storage battery does require attention, but not skilled attendance. The most important thing is to give it regular attention. Do not leave it for weeks or months till some fault develops, but treat it like other machinery, overhaul it regularly, and prevent the occurrence of any fault. A method I have found to be very good in looking after large battery plants is to have voltmeter and hydrometer readings regularly, say, once or twice a week, and every day overhaul thoroughly one cell, emptying out the acid, cleaning, if necessary, and putting everything in proper order. By doing this in the proper rotation every cell is examined, say, twice a year, yet the time required is hardly noticed, being only an hour or so every day. In this way the efficiency of a battery can be kept high, and results obtained which will put on very different complexion in some electric light stations. There are many stations in this country which are running the day load at a loss, or are losing business by not supplying current at all in the day. To these stations a battery plant would be invaluable, and would give a very different result when the balance-sheet is taken off. In many cases it would be best, of course, to leave the battery in the line always, and then when the general plant is running the battery acts as a regulator, taking up any fluctuation in the load, relieving the generating plant and keeping the potential constant. Again, in some stations the load curve takes the form of a sharp peak for a short time during the evening, when most of the lights are in use. A battery will assist the dynamos during the period of maximum load, and it removes the necessity of providing a generating plant which will only be used for a very short time during the 24 hours, standing idle and unprofitable the remainder. There is another question, too, which electric light men have to face: how can we profitably reach the outlying districts with our direct-current main? Here, again, the battery plant proves valuable; small sub-stations in the outlying districts can be built for the batteries, and these can be charged in series at, say, 400 or 500 volts, and the current distributed at the required pressure.

Mr. DeCamp observed: I happen to know something about the condition of the Germantown plant. The objection seems to be that they had an unprofitable day load that prevented them from making any money or as much money as they thought the station ought to earn. I think that came from the fact that before going into the day business the station had been fairly profitable. But looking into that matter one time for a friend of mine who was interested, I concluded that the loss of the day load was sufficiently absorbed by the profit on the profitable part of the business, and I so stated. I heard nothing more of it until the batteries were introduced, and I have been told by the company that that has stopped this loss. Now, I would like to know whether in the experience with the battery—because it is a small one, it takes up about the day load of the business, as I understand it—whether the use of the battery has done anything more than to save the loss which the station made while it was running an unprofitable day circuit: or, in other words, knowing what the profits or results of the station were previously to the introduction of the day business, have the real substantial results increased since the introduction of the batteries in proportion to the increase of their business, or whether it has simply been a saver of what they lost.

Mr. Nicholls remarked: I have a question that I think can be answered at the same time. Some of the gentlemen—one, at all events—referred to the Germantown station and set forth the great advantages gained by reason of the storage battery taking care of the day load; that previously it was necessary to run the dynamo to take care of that load, and, if I understood him correctly, it took about 60 amperes. As I understand it, that was an ideal case in which a storage battery could work to advantage. I am very much interested and have been giving a good deal of consideration to the storage battery question. We have quite a heavy day load. It would not pay us to run a day load with the storage batteries. The day load we run on the three-wire system, the same as we run our lights, with 600 amperes. It will average at the present time all through the night, from 12 o'clock to 7 o'clock in the morning about 700 to 800 amperes. If we could have an accumulator to take care of that load, it would be an advantage to shut down our station and do with one shift of hands. My difficulties may be the same as the other gentlemen of the convention, and if anyone interested can give us the information we require, it would be an advantage to us.

Mr. Wright said: I am connected in a semi-official capacity with the Germantown Electric Company. As you have been told, in December, 1892, that company adopted a chloride battery. The battery was not put in before we had thoroughly informed ourselves as to the amount we were losing from the operation of the day circuit. We made very careful tests. All the stations with which I am connected are conducted on the continuous-day principle. We weigh the coal, measure the water, count the carbons, and we get it down just as fine as we can. We had the benefit of the continuous test at Germantown, supplemented by a test of two weeks' duration, which I made myself on the day circuit. I found that the amount paid for the day circuit was exactly the amount of our total loss by the entire incandescent business, which is composed almost half and half of direct current (220 volts) and alternating current (1,100 volts) distribution. You can readily see that amount of income from the day circuit should be added to that amount, and the loss from the day circuit should be the amount remaining. I am not at liberty to state this amount. But the year's experience showed a saving which has been stated as somewhere around 2,500dol., and that saving is only figured on the rougher items, and figured from my memory, as I did not have the exact particulars with me. There are some items, such as incandescent lamp renewals, which you can readily see would enter in, that were not included. The amount saved by the year's operation of the storage battery amounts to 700dol. The output was small. The average output on each side would be from 30 to 40 amperes from dawn to dusk. I would say, further, that the amount of direct-current distribution is just one-half the incandescent business of the station. There is one point about this battery that I ought to mention. At Germantown we have doubled the lamp capacity of our dynamos. The load figures for December showed us that if we were going to do as well this year as last year in the way of extension, we would have to look out and put in more direct-current machinery, and in the annual estimate that was included.

Mr. Barstow asked: What was the rate of interest figured on the investment?

Mr. Wright replied that when the old battery was put in, only 25 per cent., or rather the depreciation was figured at 25 per cent., we allowing for that depreciation. The new battery earned about 35 per cent. on the amount of the investment during the year it was in operation.

Mr. Nicholls: You say that it showed a depreciation of 25 per cent. in one year—will you explain that?

Mr. Wright said: I would rather not answer that question, and I may as well state the reason. Battery No. 1 was put in. It was a very small battery. I have said that the average load was about 40 amperes. The load at times during last summer, when we had motors, got over 200 amperes, and that battery had to do the work. I cannot speak of the depreciation, for the reason that the battery was taken out, and the battery was not in as good shape as when it was put in. We could see evidence of the depreciation, but we have sufficient faith in the battery after one year's experience to put in a battery with two and a half times the capacity. We started with the smallest battery we could buy, but we could not limit our output. Our output consisted of motors for testing, and the current was "out of sight" as compared with the capacity of the battery. I considered that the conditions for the operation of that battery were adverse, and while it showed from a condition of depreciation when it was taken out after a year's service, the evidence was sufficient to warrant us in sending for one having two and a half times the capacity.

BOUND VOLUMES.

Vol. XII. of new series of "The Electrical Engineer" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

A SILVER LINING.

We have been constrained lately to give considerable prominence to the sayings and doings of our cousins across the Atlantic, because in their meetings they are given to discuss practical questions. Although, however, there are a number of questions thus discussed which might well claim our attention, there is at home a question of the greatest promise which cannot be neglected. It is well known that our sympathies are in favour of municipal action whenever such action is possible, but there are numbers of cases where such action is impossible, the work being handed over to private adventurers. The question, then, is, ought investors to support supply companies? and we think the answer is an emphatic "yes," when such companies are intended for real work and not for mere Stock Exchange transactions. Leaving aside the question of municipal action, it may be well to consider the prospects of an investor in a well-conducted supply company. It ought never to be forgotten that the initial outlay in equipping a central station is large, out of all proportion to its immediate return. You must equip partly for the future as well as for the present. Thus the total capital expenditure is not immediately remunerative. But how is this matter working out? Experience is showing that within a very short period the well-conducted concerns are paying smaller or larger dividends to their shareholders; hence, as time passes on and the business is more and more developed, the investors will be in a position not worse than those who have invested in gas concerns. The quantity of energy consumed is bound to increase, and even when reduction in price is made experience shows that the total return is very soon augmented. If the management is wide awake, the shareholders more probably gain by reducing the price than lose. It may cost threepence per unit to generate and distribute a couple of million of units, which may be sold at sixpence, thus giving a gross return of fifty thousand pounds at a cost of twenty-five thousand pounds—a net return of twenty-five thousand pounds. A reduction to fivepence as the selling price, if it double the quantity sold, might enable and possibly would enable it to be produced at twopence halfpenny per unit, when the net return would be over forty-one thousand pounds as against twenty-five thousand pounds at the higher price. A high selling price in several instances is killing the enterprise, when a much lower price would probably return large profits. What we are endeavouring to show is this: that investors ought to be gratified rather than frightened at the necessarily large initial outlay on central stations—in fact, we are almost inclined to say the larger the outlay judiciously and properly expended, the better; as this outlay will fructify at even more than compound interest. Again, that they ought to support the management in proposing low prices to encourage a large output rather than to support higher prices and a small output. Of course, this question is one to be considered in connection with locality, and cannot be determined in offhand fashion by irresponsible

Digitized by Google

journalists as an abstract question. We merely desire to indicate the views which we should like investors to take. The distribution of electrical energy from supply stations is a business that *must* grow, and as the expenses do not grow proportionately to the supply, the net returns for the shareholders must also grow: so that if a small dividend can be earned in early days, the probability is that a good—and continuously so—dividend may be expected later on. Hence we welcome the initiation of the companies which have been, and are, and will be put before the public. This does not mean that everything will continue to be good. Unfortunately, we must expect that, with a revival of confidence in good things, an attempt will be made to float others not so good, and a careful examination must be made of each prospectus as it comes before the public.

THE HERMITE SYSTEM AT WORTHING.

We give elsewhere the report of Dr. Kelly, medical officer of health to the Town Council of Worthing, on the Hermite method of treating sewage. We give this report because the true value of a system can only be known by considering what is said against it as well as what is said for it. As will be seen from our note columns, Mr. Cooper has protested against this report as containing erroneous conclusions. It rests with Dr. Klein and Mr. Cooper to support their respective views, but we cannot help thinking that so important a subject as sewage treatment by electrolytic methods has not received the consideration due to it. Both Webster's and Hermite's systems are benefited by a secondary action—in the one oxygen is evolved in large quantities, in the other chlorine. Still, the exact method of action is not what we want to know. Town councils and sanitary officers must first be satisfied that the system is effective, and then comes the question, at what price? The latter is really of less importance than the former, for with the increase of town population some method of treating sewage other than those in vogue now must come into operation. Our impression is that electricity will be the active agent that will be used, hence our desire to see the whole question calmly thrashed out.

THE FRENCH CHAMBER OF ELECTRICAL INDUSTRIES.

A report is given in the *Bulletin International de l'Electricité* of a recent meeting of the Chambre Syndicale des Industries Electrique, a body which corresponds to our Electrical Section of the London Chamber of Commerce. The President stated he had received a communication from the police referring to a fire which had resulted from a short-circuit in a building, and suggesting that the attention of electricians should be called to the measures of precaution which should be observed in such matters. The speaker had profited by the circumstance to call the attention of the authorities to the utility of the Bureau de Contrôle, established by the Chamber to prevent such accidents.

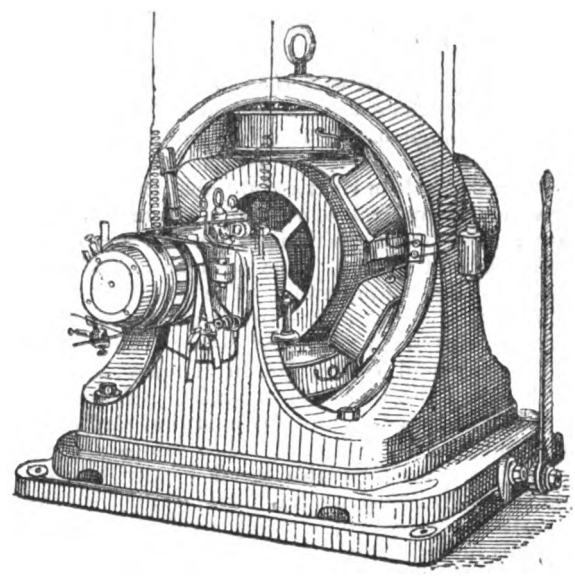
The president informed the members that the Chamber of Deputies had appointed a commission, with M. Georges Berger as president, to enquire into projected legislation on the laying and arrangement of electrical mains. It was to the interests of electrical industries to amend as far as possible the text of the proposals of the authorities, although the wording had already been conceived in a liberal spirit. It would be advisable, for instance, to get inserted a new clause providing that in the case of the Government having to modify its telephone lines owing to the establishment of new conductors for the service of the public, such as electric tramways, the cost of the same should not fall upon the *concessionaires*.

Mr. Picou, the director of the Bureau de Contrôle, next gave an account of its operations during the season. They had subscribers on January 1 amounting to 13,500 lamps. The number of visits made to installations was 101, and the number of tests of meters made was 77. The receipts of all kinds amounted to 14,597f., or, say, £584. This was a satisfactory result, and a good development was anticipated. A modification of the tariff was agreed to.

The question of taking part in the Antwerp Exhibition was considered. A committee was appointed to enquire into the advisability of a proposal which was made that a joint display should be made by French electricians, it being argued that greater economy could thus be effected than by independent exhibits, besides other advantages being attained.

A NEW DIRECT-CURRENT ARC GENERATOR.*

The results of extended and elaborate experiments, carried on for a long time by the Westinghouse Electrical and Manufacturing Company, with a view of obtaining a dynamo that would better fulfil the requirements of direct-current arc lighting than any heretofore in use, are embodied in its new direct-current arc machine, which we illustrate.



Though the new machine differs very radically in construction from former types, it belongs to the well-known open-coil continuous-current class, which is acknowledged to offer special advantages for arc lighting work.

A machine of this class delivers a uni-directional though not continuous current, for while the E.M.F. of the terminals does not change its sign, it, nevertheless, pulsates or fluctuates. This pulsation of the E.M.F. gives a steady mean value to the current, and makes it particularly adapted for arc lighting, as its pulsating character keeps the mechanism of the lamps in a slight but constant vibration, thereby rendering them less liable to become slow in action or altogether fail to feed.

The new machine in general appearance is similar to the Westinghouse standard alternating-current dynamos—that is, it consists of a circular cast-iron yoke parted horizontally and having inwardly projecting poles. The armature is of the toothed type with lathe-wound coils, especially heavily insulated.

The public are thoroughly familiar with the advantages of the toothed armature, which avoids the use of band

* From the *Electrical World*.

Digitized by Google

wires and allows the replacing of an injured coil with but small outlay of time and money. The use of lathe-wound armature coils secures any desired degree of insulation—a most important point in the construction of every arc dynamo. The armature is supported in self-oiling bearings with spherical seat, so that the machines are self-aligning. The bearings are cast solid with the lower half of the field, thereby securing great strength and rigidity of construction.

A particularly strong point claimed for the machine is the system of regulation. It has absolutely no regulating devices or wall traps, such as have heretofore been the accompaniments of all constant-current machines. Regulation is effected, as in the Westinghouse alternating-current arc machines, by the reactive effect between the winding of the field and the armature. The generator may be short-circuited and run without injury, and is absolutely self-regulating throughout its entire range of load.

With the use of direct currents, the commutator has always been considered the weak point of the system. Consequently, particular attention has been paid to the securing of satisfactory results here. This has been accomplished by the use of a new-type commutator, which presents a large bearing surface for the brushes, and which has the segments separated by $\frac{1}{2}$in. of insulation, so that the machine is particularly free from vicious sparking. Four sets of copper brushes collect the current without the use of "blow-outs" or other troublesome devices intended to avoid sparking.

The field coils are connected in series with one another. The exciting current is supplied from a separate low-voltage machine, so that the use of high potentials in the field windings—a menace to insulation and life—is avoided. An efficiency of over 90 per cent. is claimed for the new machines, which far exceeds anything heretofore available, as the best direct-current series arc machines are ordinarily very inefficient. The speed varies from 750 revolutions for 60-arc 9$\frac{1}{2}$-ampere machines to 950 revolutions for 25-arc machines.

The lamps supplied with the machine are of the rack feed type, affording the excellent method of regulation secured in the Westinghouse constant-potential lamps. In the construction of these lamps particular attention has been paid to making them rigid and durable, thus enabling them to give long continued service with a minimum amount of repairs. The lamps are designed to suit the requirements of all kinds of service. The outdoor lamps are plain in appearance, but weatherproof. The indoor lamps are made in a variety of forms with brass or galvanised iron mountings, and with plain or fancy globes. The lamps use a plain or coppered carbon $\frac{5}{8}$in. in diameter, and they will give 14 hours' life with one trimming. These lamps are designed to be used on any direct-current series arc system which supplies 9$\frac{1}{2}$ amperes. The lamps are supported from strong non-combustible metal hanger boards. Each lamp is supplied with an automatic cut-out, so that when the carbons are burned, or if any accident happens to the lamp, it is automatically cut out of circuit without disturbing the other lamps in use.

POLYPHASE TRANSMISSION.*

BY CHARLES F. SCOTT.

(Continued from page 375.)

The curves show that if the power factor be 100 per cent., as it is with incandescent lamps, the inductive drops for various counter or inductive E.M.F.'s are ·02 per cent. for 2 per cent.; ·08 per cent. for 4 per cent.; ·18 per cent. for 6 per cent.; ·32 per cent. for 8 per cent.; ·50 per cent. for 10 per cent.; 1·2 per cent. for 15 per cent.; and 2·0 per cent. for 20 per cent. The curves show that the drop increases very rapidly at first if the power factor becomes less. These relations may be elegantly determined by a simple diagram on section paper ruled in tenths. Draw an arc through a quadrant with a radius of 100. At a distance from the centre on the horizontal, equal to the power factor of the load, erect a perpendicular and extend it to the arc. This line represents the counter E.M.F. of the load, and its value, read directly on the scale, gives the counter E.M.F. in per cent. of the E.M.F. upon the load. From the intersection of the arc draw a horizontal line outside the circle, equal on the scale divisions to the per cent. in terms of the E.M.F. on the load which would be required for sending the normal amperes continuous current through the line resistance.

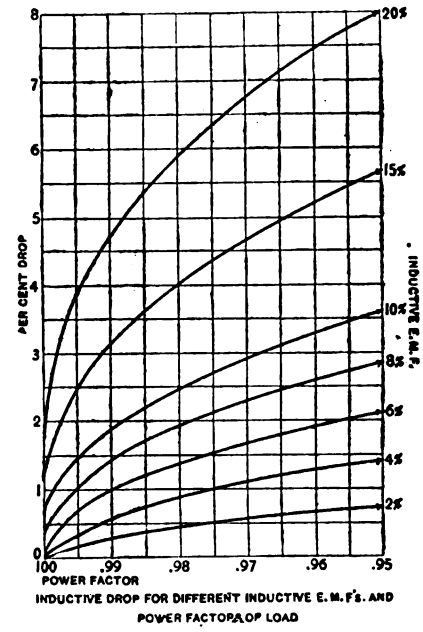


FIG. 12B.

From the end of this horizontal line draw an upward vertical equal to the counter E.M.F. of the line expressed in per cent. of the E.M.F. on the load. A line from the centre to the upper end of this vertical represents in direction and magnitude the E.M.F. which must be impressed on the circuit. If, from the same centre, an arc be drawn through this point to the base, the scale divisions on the base between the two arcs measures the total drop caused by the line in terms of the E.M.F. on the load.

SELF-INDUCTION IN TRANSFORMERS, ETC.

Self-induction exists in line, generators, transformers, secondary wiring, and sometimes in the load. In each case the effect of the self-induction upon regulation depends largely upon the self-induction of the total load which it supplies. Thus, the regulation of a generator depends upon the total self-induction of the line, transformers, and load. Again, the regulation of a line supplying converters depends both upon self-induction of the converters as well as that of the useful load. The same analysis, diagrams, and tables which have been used above in connection with the line will apply to the transformers and approximately to the regulation of the generator.

An ordinary transformer has primary self-induction and a secondary self-induction and a mutual induction, which becomes a ready source of very complicated and perplexing analysis when the complete action is described in theoretical terms. Practically, however, the action of the self-induction in the transformer may be expressed in a very simple way, and it is readily seen that this self-induction has a very important bearing upon the regulation of the transformer. The regulation of the transformer is very similar to that of a line, as explained above. If the secondary coil be short-circuited, the E.M.F. on the primary may be adjusted so that the normal full-load current passes through the apparatus. This E.M.F. corresponds very closely to the E.M.F. required for sending current through a short-circuited line, and in ordinary transformers is practically equal to the counter E.M.F., and may be considered equal to it.

A transformer may be taken for experiment in which the E.M.F.'s are 1,000 volts and 100 volts. If five volts, or $\frac{1}{2}$ per cent., is required for sending through the primary a continuous current equal to the normal full-load current of the transformer, and if a similar E.M.F. in the secondary is half a volt, or $\frac{1}{2}$ per cent., then the ohmic loss in the transformer is 1 per cent., and the drop in pressure at the

* Paper read before the National Electric Light Association, Washington.

Digitized by Google

secondary terminals between no load and full load will be 1 per cent., if the self-induction be negligible. If, however, there is a self-induction, so that 100 volts, or 10 per cent., is required for sending the normal current through the primary when the secondary is short-circuited, then the drop in pressure is in general greater than 1 per cent., depending principally upon the character of the load. The load may be non-inductive, as lamps, or it may be more or less inductive. The experiments described above, in which a line had the same per cent. ohmic and inductive characteristics as the converter just described, apply to the converter as well as to the line. The drop on such a converter therefore, may vary from 1½ to 10 per cent. when delivering its rated current. Arc lamps or fan motors will produce a very much greater drop than incandescent lamps. The power factor of an alternating-current arc lamp varies considerably, but in a number of cases has been found between 85 and 90 per cent. The drop, when incandescent lamps are replaced by arc lamps on the transformer just described, increases from about 1½ to 5 or 6 per cent.

A secondary line, if it carry a large current, may have a counter E.M.F. of several volts. This may not be enough to increase appreciably the drop in the line between the transformer terminals and incandescent lamps. But the transformer, however, delivers current to the secondary circuit and to the lamps, so that the regulation of the transformer may be affected by the self-induction of the secondary circuit. Cases have occurred in which transformers of a very old type possessing high self-induction were supplying very large secondary currents, and the resulting drop in the transformers was increased several per cent. For example, a circuit of No. 0000 B. & S. wire supplying 100 amperes to 50-volt lamps at a distance of 100ft. has an ohmic drop of 2 per cent. The constant for counter E.M.F. of this circuit, if the wires be 6in. apart, is ·022. The volts at 16,000 alternations are $·022 \times 100 \times ·1 \times 16 = 3·52$, or 7 per cent of 50 volts. The inductive drop in the line corresponding to 7 per cent. is ·25 per cent. The power factor of the aggregate service of the transformer is the second side of a right-angle triangle, of which 7 is one side and 100 is the hypothenuse. This is 90·7, which is the power factor of the total load on the transformer. If the self-induction of the converter be 10 per cent., the inductive drop is 1·2 per cent.; if 20 per cent., the inductive drop is 3·4 per cent., and if 30 per cent., the inductive drop is 7 per cent. The aggregate drop in the converter and secondary circuit in the latter case would be, say, 2 per cent. for ohmic drop in transformer, 2 per cent. ohmic drop in line, 7 per cent. inductive drop in transformer, and ·25 per cent. inductive drop in line, or a total of 11·25 per cent. The necessary ohmic drop is 4 per cent., and the inductive drop resulting from self-induction in transformer and line is therefore 7·25 per cent. If the number of alternations be reduced to 7,200, the inductive drop would be reduced from 7·25 per cent. to 1½ per cent.

Ordinary Tests upon Transformers.

The practical bearing of the self-induction of a transformer upon its regulation and the exact relation between the two does not seem to be clearly recognised, and even Dr. Hopkinson and Dr. Fleming, who have made very exhaustive tests upon transformers, comparing different methods of testing and different types of transformers, have not brought out this point. Attention is given to the exact form of the current wave, and measurements upon the iron losses are attempted within very close limits of error. Their measurements upon the regulation of the same transformer, however, vary from 2 per cent. to 2·4 per cent., or one measurement is one-fifth greater than the other. The presence of slight induction in the secondary load would have caused a very considerable increase, and it is probable that the difference in the measurements made were due to difference in the self-induction in the instruments used, or in the load at the time the tests were made. No note is made of the effect of the self-induction of the load upon regulation, although regulation is one of the most vital points in the practical use of transformers. Even the temperature at which the drop was measured is not stated, although the resistance of a transformer, when continuously working, may be 20 per cent. greater than when cold. The elements of practical importance in a transformer are (1) the iron loss in respect to the efficiency; (2) the regulation in respect to the satisfaction of service; and (3) the temperature to which the insulation is subjected, as affecting the life of the transformer. In the ordinary tests by theoretical men, the iron loss is measured to a very high degree of refinement, although the iron loss in transformers is the one thing which cannot be controlled, and is certain to vary 10 or 15 per cent. in commercial manufacture of transformers of the same size. The wave form of E.M.F. on different dynamos, or the difference in form under different conditions of load on a circuit, may make the loss under different commercial conditions vary several per cent. This renders more refined measurements of no practical use, unless the conditions are stated. The temperature of the iron also affects the loss. The full-load efficiency is usually given as if it had a great deal of importance, whereas the losses in copper during 24 hours ordinarily amount to but a trifling per cent. of the total losses. The regulation, and the temperature to which the insulation is subjected, and which it is able to stand, are generally not mentioned in reports of tests. The usual investigations, and the papers published on the alternating-current transformers, may, perhaps, accurately express many facts in complicated formulæ, but the practical bearing of these points in every-day working seems to be totally ignored.

Mutual Induction.

If two circuits be run on the same pole line they act as a transformer in which one circuit carrying current may act as a primary, and induce E.M.F. in the other as a secondary. If the latter circuit is connected with the same dynamo, and is delivering current, its E.M.F. will be slightly raised or slightly lowered by the effects of the first circuit.

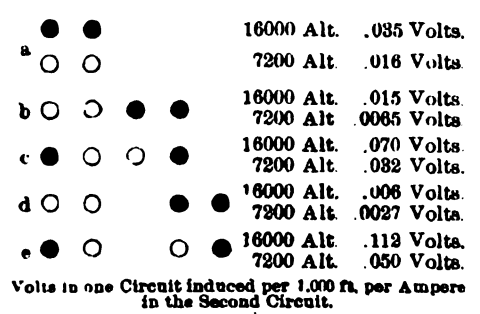

Fig. 13.

Conversely, the second circuit will have similar effect upon its neighbour, raising or lowering its pressure by a slight amount. If the two circuits be connected to different dynamos which are running at slightly different speeds, then the E.M.F. induced by one circuit upon the other will sometimes increase, and at other times decrease the E.M.F. of the circuit, depending upon whether the two currents at a given moment are flowing in the same or in opposite directions. This fluctuation may cause variations in the intensity of the lights supplied. It is readily detected in the service of some central stations, and is, of course, most marked at times of full load, as the induction of one circuit upon another depends upon the strength of the current carried. The fluctuation due to this action may be readily distinguished from that due to slipping of belts or irregularity in engine speed, as the induction effect is due to the difference in alternations between two machines, and the speeds of the two machines are apt to vary slightly from time to time, giving a gradual variation in the rate of fluctuation of the lamps. The fluctuation due to mutual induction of lines occurs only at the end of the line, and is not observed in the station, while the other causes affect the station lights also. The number of volts E.M.F. set up in one circuit by a parallel circuit depends upon the current, the distance which the lines are parallel, and upon the relative positions of the four conductors. The distance between wires may be 6in. or 6ft. without affecting the mutual induction, provided the relative positions be unchanged. Several dispositions of circuits are shown in the accompanying figures, and the number of volts per thousand feet at 7,200 and at 16,000 alternations which are induced in either circuit by one ampere in the

Digitized by Google

other are given in connection with each figure. The number of volts required for producing objectionable flickering in the light depends upon the voltage of the lamps in service, the efficiency at which they are run, and the general surroundings in which they are placed, notably the relation of lamps to reflectors, white walls, etc., and the general disposition of the customer.

An E.M.F. of $\frac{1}{2}$ per cent. induced in one circuit by another can in some cases be detected, and usually more than 1 or 2 per cent. will cause objectionable flickering.

Methods of Reducing Mutual Induction and Self-Induction.

The mutual induction is reduced by bringing the wires in each circuit close together and separating the circuits. The effect of this mutual induction may be neutralised by crossing one of the lines at its middle point, so that induction in the first half of the line is counteracted by the induction in the second half. It is readily noted that the effect of self-induction in a circuit is reduced as the wires are brought close together, or if each conductor be divided into several wires in multiple and separated. The effect of self-induction is diminished as the number of alternations is reduced. The following points are also to be noted in connection with inductive drop. If the power factor be nearly 100 per cent., the inductive drop increases as the square of the counter E.M.F. If the E.M.F. of the circuit be increased, and the same power delivered over the same circuit, the per cent. counter E.M.F. decreases as the square of the E.M.F. delivered, and the inductive drop decreases approximately as the fourth power. If the number of alternations be decreased the counter E.M.F. decreases directly, and the inductive drop decreases as the square. The inductive drop at 7,200 alternations is less than one-fourth of that for 16,000 alternations for ordinary power factors.

Capacity in Lines.

The static capacity in ordinary lines is usually small, and its effect is not of importance unless the line be very long or the pressure be very high. The general effect of capacity in the line, or of connecting condensers to the line, is to lessen the current from the generator which is required for supplying inductive load and to reduce the drop due to self-induction. The use of condensers for this purpose may lead to very considerable gains in circuits where the self-induction of line or of load becomes considerable. If an inductive circuit or transformer supply current to condensers, the E.M.F. may increase instead of decreasing, as it does with inductive load.

Polyphase Circuits.

The subjects which have so far been considered apply to single-phase as well as polyphase circuits. The effects of self-induction will be brought to the attention of the electrical engineer much more prominently in connection with polyphase work, however, because larger alternating-current enterprises will be carried out with the polyphase system and power work involving variable power factors will be a large element in this system. There are, in addition, several problems which relate distinctively to polyphase working. One of these is the most suitable number of phases to be used. The two-phase system and the three phase system are both in operation, and while it is admitted by the adherents of each system that there is no fundamental difference between them, yet each has specific characteristics giving particular advantages.

(To be continued.)

A UNIVERSAL SHUNT-BOX FOR GALVANOMETERS.

In our last issue we reproduced the paper read before the Institution of Electrical Engineers on "A Universal Shunt-box for Galvanometers," by Prof. W. E. Ayrton and Mr. T. Mather. Prof. Ayrton now writes to make certain additions.

At the end of the first or opening paragraph, after the words "had been increased," add the following: "by an amount which depended on the details of the construction of the particular galvanometer, and on the adjustment of the controlling magnet."

The following additions are to be made at the end of the paper:

It is well known that with the ordinary method of constructing shunts the resistance of the circuit is altered when the shunt is varied. An interesting question therefore arises whether this change in the resistance of the circuit is greater with the method that we have proposed of constructing a shunt or with the ordinary method. With the ordinary method of keeping the main

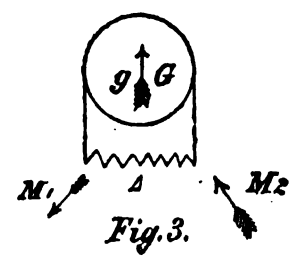

Fig. 3.

leads, M_1, M_2 (Fig. 3) permanently connected with the galvanometer, G, and of varying the current through the galvanometer by altering the resistance, s, of the shunt, the change that is produced in the resistance of the circuit on applying this shunt is, as well known, *from* g to $\frac{s\,g}{s+g}$—that is, the resistance is diminished *by* $\frac{g^2}{s+g}$. If, then, the shunt be such as to allow $\frac{1}{n}$th of the current to pass through the galvanometer, s equals $\frac{g}{n-1}$, and the resistance in circuit is diminished by $\frac{n-1}{n} \times g$ when this shunt is applied. For example, if n be 10, the resistance of the circuit will be diminished by nine-tenths of g.

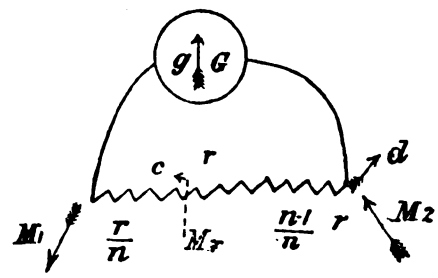

Fig. 4.

With our proposed method of keeping a *fixed* resistance, r, attached to the galvanometer, G (Fig. 4), and of varying the current through the galvanometer by varying the connection of one of the main wires—for example, by moving the main wire, M_2, from the point d to the point c—the resistance of the circuit is altered *from* $\frac{r\,g}{r+g}$ to $\frac{r}{n}\left(\frac{\binom{n-1}{n}\,r+g}{r+g}\right)$—that is, the resistance in the circuit is diminished *by*

$$\frac{1}{r+g}\left\{\frac{n-1}{n}\cdot r\,g-\frac{n-1}{n^2}\,r^2\right\} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Now, this expression depends not merely on the values of n and g, but also on the value of r. If r is selected so as to be less than $n\,g$, the expression (1) is positive—that is, the resistance of the circuit is *lessened* by shifting the main M_2 from the point d to the point c; whereas if r is selected so as to be greater than $n\,g$, the expression (1) is negative, which means that shifting the main M_2 *increases* the resistance of the circuit. Lastly, if r be chosen so as to be exactly equal to $n\,g$, shifting the main produces *no change whatever* in the resistance of the circuit, so that the current *now* passing through the galvanometer after shifting M_2 is exactly $\frac{1}{n}$th of the current that *previously* passed through the galvanometer, for the current in the main circuit undergoes no change, whether the resistance of the circuit be large or small.

By selecting r, then, so that it is roughly equal to $n\,g$, our proposed arrangement gives the following result on shifting the main M_2 from d to c:

(*a*) If the resistance of the rest of the circuit be large compared with that of the galvanometer, the current that *now* passes through the galvanometer is exactly $\frac{1}{n}$th of that which *previously* passed, whatever be the temperature.

(*b*) If the resistance of the rest of the circuit be even small compared with that of the galvanometer, the current that *now* passes through the galvanometer is very nearly $\frac{1}{n}$th of that which *previously* passed, whatever be the temperature.

Contrasted with this, we have, with the ordinary method of applying a shunt, the result:

(*a*) Even if the resistance of the rest of the circuit be large compared with that of the galvanometer, it is only when the tempera-

Digitized by Google

ture has one definite value that the current that *now* passes through the galvanometer is exactly $\frac{1}{n}$th of the current that *previously* passed.

(*b*) If the resistance of the rest of the circuit be small compared with that of the galvanometer, the current that *now* passes through the galvanometer is far greater than $\frac{1}{n}$th of the current that *previously* passed.

Lastly, whatever be the values of g, r, and n, our method of altering the current through the galvanometer produces less change in the resistance of the circuit than the ordinary method. For, as already seen, with the ordinary method of applying a shunt the resistance of the circuit is diminished by $\frac{n-1}{n}g$, while on moving the main M_2 from d to c with our method, the resistance of the circuit is diminished by

$$\frac{1}{r+g}\left(\frac{n-1}{n}rg - \frac{n-1}{n^2}r^2\right);$$

therefore the ordinary diminution of resistance minus the diminution of resistance in our case equals the difference between these expressions, which is

$$\frac{(n-1)(ng^2+r^2)}{n^2(r+g)} \quad \ldots\ldots\ldots \quad (2)$$

Now this expression (2) is always positive when n is greater than unity: therefore our method of shunting produces the *less* change in the resistance of the circuit in all cases.

THE HERMITE PROCESS OF TREATING SEWAGE BY ELECTROLYSED SEA-WATER.

REPORT OF THE MEDICAL OFFICER OF HEALTH OF WORTHING.

We reproduce below the report prepared by Mr. C. Kelly, M.D., the medical officer of health for the borough of Worthing, on the Hermite system of treating sewage as experimentally tested at Worthing. The report has been presented to the Sanitary Committee of the Town Council:

In accordance with your request, I have examined carefully the process which has lately been carried out in Worthing for the treatment of sewage by M. Hermite. After having made numerous experiments, and having obtained the assistance of Dr. Klein, F.R.S., and Dr. Dupré, F.R.S., for a bacteriological and chemical enquiry, I now submit to you the following report:

The whole of the plant has been erected under the direction of M. Hermite, and the method adopted is that carried out by the inventor himself, so that this report does not deal with the treatment of sewage at the outfall, nor with the mixed sewage of a town, but only with such sewage as the author of the process has seen fit to include.

The Hermite solution is obtained by the partial electrolysis of sea-water. Two galvanised iron tanks, each capable of holding 1,000 litres, or 220 gallons, are placed side by side, while between and above them an electrolyser is placed in a small metal box. There are four rows of vertical rods, covered in their lower half by a mesh of fine platinum wire, which dip into the sea-water contained in the box; each row contains 11 such rods. Between these rows circular discs of zinc revolve when the machinery is in motion. The current, generated by a dynamo which is driven by a portable steam-engine, passes through the sea-water between the electrodes of zinc and platinum, and in doing so it is said to decompose the magnesium chloride, and so to produce a disinfecting fluid.

A gallon of ordinary sea-water contains about 2,275 grains of combined chlorides in solution, of which magnesium chloride amounts to about 256 grains, the rest being nearly all sodium chloride. It is stated that the magnesium chloride is alone decomposed, and that the sodium chloride serves as a conductor. It takes about 2 to 2½ hours to convert 220 gallons (1,000 litres) into a disinfecting fluid of a strength equal to 0·75 gramme of chlorine per litre, but M. Hermite says that a solution containing 0·30 gramme of chlorine per litre is sufficient for his system. No account is given of the chemical nature of the substance produced by his process; it is said to be an oxygenated compound of chlorine, but no chemical formula is given. The solution has a smell of a weak solution of bleaching powder, and M. Hermite contends that his solution is of a similar nature, with this difference, that magnesia takes the place of lime in a bleaching fluid.

Bleaching fluid is a solution of chlorinated lime, and his solution may then be called chlorinated magnesia. In each case hypochlorous acid seems to be produced in combination with a base, and this acid is one of the compounds of chlorine with oxygen. When good commercial bleaching powder is treated with distilled water, a certain proportion is dissolved, and this fluid will give a strength equal in effect to 25 or 30 grammes of chlorine per litre. Such a liquid gives off a strong smell of hypochlorous acid, and it has active bleaching power when treated with a diluted mineral acid. The strongest Hermite solution which I have examined contained 0·75 gramme of chlorine per litre, or 0·52 grain per imperial gallon. On several occasions the strength was much less, amounting only to 0·22 gramme of chlorine per litre, while in most of the experiments a strength of 0·44 gramme to 0·51 gramme was obtained, or a quantity in excess of that (0·30 gramme) which it is claimed will suffice for disinfection.

The strength of this standard may be better understood when I say that it is 60 times weaker than a saturated solution of good bleaching powder. The Hermite solution loses its strength when kept for a few days, even in closed vessels. Two such samples lost nearly one-twentieth of their strength in two days. The solution contains no free chlorine, as has been often alleged, and it does not redden litmus paper. It will decolourise sulphate of indigo at once, and its strength is thus ascertained: A solution containing a known quantity of arsenious acid is taken, and of this 5 c.c. are placed in a small glass beaker, into which two or three drops of indigo solution are added, so as to give the liquid an intense blue colour. On adding the Hermite solution no change in colour takes place until the arsenious acid is changed into arsenic acid, and when this is completed the blue colour disappears, and the liquid turns to a pale yellow-brown colour. The strength of the solution can thus be quickly ascertained. The weaker the solution the more is required for decolouration. When treated with dilute hydrochloric acid, it gives off chlorine, and it will then bleach reddened litmus paper.

There is no treatment of sewage by electricity as in Webster's method. Electricity is only used to decompose the sea-water, and the altered sea-water so produced is allowed to act chemically on sewage. The process has only been carried on upon a small scale in West-street. In yard A the dynamo and the tanks are placed, and then the electrolysed fluid is pumped up into some store tanks, whence it is distributed for use as occasion may require. In yard B two new water-closets have been recently put up, and these are in direct connection with one of the syphons used in the process. In yard C is a second syphon, also sunk in the ground, which receives the treated sewage from the similar syphon in yard B, and also the ordinary sewage from 14 cottages in West-street. The store tanks in yard A are filled from the dynamo tanks; they are made of galvanised iron, and the water is distributed from them to the flushing-tanks, but not to the sinks of each cottage. There is also a galvanised iron pipe (attached to the public water-main) which leads to one of the store tanks, and thus the tanks can be filled with the town water as well as with the treated sea-water, so that if there were not enough of the latter produced the cottagers would not be without a supply for flushing purposes. It would, indeed, be well worth while to cease using the electrolysed sea-water for a time, and to see what would be the effect of sending through the temporary system (1) sea-water and (2) town water for a period of seven days each. No further arrangements would be required, and it would be interesting to note what difference would be met with when the three methods were compared.

There is a difference in the arrangement in the two yards B and C. In yard B there are two new water-closets erected, each provided with a short hopper basin and trap delivering into a short and partly open drain, which leads directly to the syphon. Each closet has a flushing-tank which holds from two to three gallons, and which is supplied directly from the store tanks in yard A. No storm water nor subsoil water nor any dirty house water can pass down this drain, and the syphon only receives such material—liquid or solid—which has passed through the closets. There is, however, a tap in this yard which is supplied from the store tanks, and whence water can flow at once into the temporary drain, and so into the syphon without going through the closets. The syphon in yard B acts as an intercepting trap whereby anything smaller than the meshes of the cage can pass away into the sewer. It is clear that since any solid matters are, as a rule, broken up on or before their arrival at the syphon, they will pass on at once to the sewer with each successive flush, or whenever there is a current of water issuing from the tap. After a closet has been in use, the next flush will allow a certain amount of fresh fluid to enter at the top of the syphon, which then cause a similar amount of the contents to be displaced and flow forward towards the sewer. If this process be repeated a few times, without any more excreta passing from the closets, the original fluid will be all driven forwards, and the syphon will then be full of water only. It matters not how often these closets are used, for if after such use sufficient clean water passes down the drain, the syphon will soon be filled with this clean water, and any samples taken from the small drum beyond the syphon bend will be samples of clear water only; and if the electrolysed fluid be used, the samples will be those of electrolysed fluid only. The only solid matters left in the cage will be portions of papers which are too large to pass through the perforated holes of the cage. At certain times there must be some solid matter, and then the effluent is more or less tinted.

The case is different with regard to the arrangements in yard C. Here not only the closets but the dirty house water from 14 cottages, as well as the treated sewage from yard B, is constantly passing into the syphon. There is also a considerable amount of storm water, which flows from the roofs and yards of the houses when there is wet weather. The amount of sewage will be very small at night time, but during working hours, and especially on washing days, a large amount of dirty water must constantly be running from the houses away to the sewer. One can tell roughly the nature of the fluid by its appearance before it enters the syphon; sometimes it is clear and almost free from house refuse, as when there is a rainfall, and the closets and house drains do not happen to be used. At other times the fluid has the usual appearance of ordinary liquid house refuse. There is no separate tap here by which a quantity of water can be sent down from the store tanks; each closet is supplied by a flushing-tank, which is fed from the store tanks. Nevertheless, the town water being

Digitized by Google

laid on to the interior of each house, the water from the sinks and the water used for washing and cooking is free from the disinfecting fluid until it enters the drains. Any sample taken from the small drum in yard C during working hours will be sure to contain some sewage of greater or less strength. Any samples taken from the small drum or the cylinder in yard C will furnish a better proof of the efficacy of the Hermite process than samples taken in yard B, where it is possible that nothing else than the disinfecting fluid may be drawn.

When 20oz. of fresh excreta—*i.e.*, 4oz solid and 16oz. liquid—were placed in a gallon of Hermite solution there was no bleaching and no breaking up nor destruction of the solid matter; the only effect was to conceal the odour of the contents, and to delay decomposition. When to 20oz. of this treated mixture three times the amount, or 60oz., of Hermite solution were added, there was still no bleaching nor decomposition, but simply dilution of the original mixture, and the contents were partly deodorised. The Hermite solution used was of the strength indicated by 0·61 gramme of chlorine per litre. Dilution with sea-water only produced results similar to those met with when the electrolysed fluid was used, but in the latter case the colour was not so intense. Both fluids prevented the decomposition of the excreta, and the Hermite solution produced in addition a small amount of bleaching effect, When the proportion of excreta was 1 in 32 of the Hermite solution its presence was easily detected, but when a solution of chlorinated lime of similar strength was used better results were obtained, and there was complete discolouration. When strong chlorinated lime solution was tried the contents were decomposed with evolution of froth, the fluid was bleached, and the liquid soon separated on standing into a clear portion and an abundant white flocculent deposit. The change with the Hermite solution was one of dilution chiefly, and not decomposition; the resulting fluid never became clear, and there was no white flocculent precipitate. With weaker solutions obtained from the process, the results were much the same as when sea-water only was used. When dirty house water was taken from yard C, after passing through the syphon, it was nearly as foul as before entering, but any solid matters were, of course, retained when they were not small enough to pass through the holes in the cage; the perforated cage on the house side of the syphon acted simply as a coarse strainer. When to this treated effluent varying portions of Hermite solution were added, the chief effect again was one of dilution only, and there was but little trace of any bleaching action. In the proportion of 1 of this sewage to 10 of the disinfecting fluid the resultant was still foul. Strong chlorinated solution at once produced decomposition, followed by clearing up of the fluid and abundant flocculent precipitate.

I have tried several experiments with a view to see what effect the electrolysed fluid would have when various materials were exposed to its action for several days or weeks. To make a proper comparison three sets of bottles—each holding one pint—were filled with different liquids. In series A ordinary sea-water was used, the water being allowed to stand for a few hours, so as to allow of any sand or suspended matter to settle, and then the clear liquid was poured into each bottle. In series B a saturated solution of chlorinated lime was taken, and after subsidence the clear fluid was used to fill each bottle. In series C a similar set of bottles was filled with freshly-prepared electrolysed liquid of known strength.

It was necessary to make these three sets of experiments, so as to see what action was due to the sea-water acting alone and what was due to it after it had been treated. Since chlorinated lime water is analogous in composition to the electrolysed water, it was used to see what action it would have on the ordinary substances used in sanitary apparatus. Although very much stronger in its action than any Hermite solution, it served as a guide to point out what materials would be most affected, or what substances would resist attack. It is clear that if the stronger solution did not affect any articles which were placed in it, and which were exposed to its action for many weeks, it might fairly be assumed that they would still more easily resist the disinfecting fluid. If, on the other hand, any articles were injured or corroded by the chlorinated lime water, it would be equally fair to assume that the Hermite solution would act in a similar, but less severe, manner. The amount of harm done would in a given time be, of course, greater when the strong solution was employed, but the injury done would be chiefly a matter of time. A substance exposed to the action of the electrolysed fluid for several months might be as much injured as one exposed to the lime solution for a few days.

All the experiments were carried on under similar conditions, but all the solutions were in a state of rest. In this point they differed from what would occur in actual practice, where the fluid is constantly changing, and any rust or corroded particles could be carried away in the current and escape notice. To allow for this loss, the bottles, at intervals of a week, were partly emptied, any clear fluid was poured off, and they were refilled from the original solutions or from solutions of a precisely similar nature freshly obtained. The list given in Table A shows that on the first nine substances the three fluids had no effect. On metallic bodies, as iron and copper, the effect was very marked, but lead, zinc, and tin showed no appreciable difference.

Since iron was the metal most liable to injury, a further trial was made. Three short pieces of 1in. black iron pipe, and three short pieces of 1in. galvanised iron pipe were taken, and each piece was separately marked and carefully weighed. Four pieces (two of each kind) were then placed in chlorinated lime solution and electrolysed fluid, and the remaining two pieces (one of each kind) were set aside for comparison. The four pieces were kept in the solutions, in four separate bottles, for 19 days, when they were taken out, dried, and re-weighed.

TABLE A.

Material.	Sea-water.	Chlorinated lime solution.	Hermite solution.
Mortar	No effect.	Split into layers.	Slight flaking.
Neat cement	No effect.	No effect.	No effect.
Cement	No effect.	No effect.	No effect.
Clay	No effect, beyond crumbling.	No effect, beyond crumbling.	No effect, beyond crumbling.
Paper	No effect; no bleaching of ink on printed paper	No effect; no bleaching of ink on printed paper	No effect; no bleaching of ink on printed paper.
Indiarubber	No effect.	No effect.	No effect.
Insertion (2 ply)	No effect.	No effect.	No effect.
Water-dressed leather	No effect.	Softened.	Softened.
Oil-dressed leather:			
1. Dyed	Solution coloured brown.	Solution coloured brown.	Solution colo'red brown.
2. Thin harness	No other effect.	No other effect, beyond a white deposit on the surface of the material.	No other effect.
Copper (thick wire)	Pale sea-green precipitate and deposit on metal.	Much dark lake precipitate and deposit on metal.	Blue-green precipitate and deposit on metal.
Black iron ...	Dark-brown green deposit.	Copious formation and deposit of rust; much destruction of metal.	Abundant formation and deposit of rust with destruction of metal.
Galvanised iron	No marked change.	Slight erosion of surface and loss of zinc coating.	No marked change.
Zinc	No effect.	Slight erosion.	No change.
Tin.....	No effect.	No effect.	No effect.
Brass fittings.	Same as copper.	Same as copper.	Same as copper.

	Chlorinated Lime Solution.	Hermite Solution.
Black iron 1in. pipe.	*Marked IV.* Original weight =93·5374 grammes. Final weight =89 9048 grammes. Loss=3 6290 grammes, or 56 grains.	*Marked V.* Original weight =97·7494 grammes. Final weight =97·2310 grammes. Loss= 5184 grammes, or 8 grains.
Galvanised iron 1in. pipe.	*Marked I.* Original weight =87·2517 grammes. Final weight =81·3647 grammes. Loss=5·8870 grammes, or 91 grains.	*Marked II.* Original weight =94·1207 grammes. Final weight =94·1855 grammes. Gain=·0648 gramme, or 1 grain.

The slight gain in the last case was due to a little white deposit which adhered strongly to the surface of the galvanised iron. I have not gone into the question of cost, as that is a matter for engineers; nor into the question of trying the process on sewage when it has passed into the sewers, nor upon sewage at the outfall, since the present experiments have only been applied to houses. Besides the annual cost of producing sufficient fluid, there would be a very great outlay in putting down a fresh set of mains, pipes, and cisterns so as to convey it to each house. Moreover, each house, or each group of small houses, would require to be furnished with a syphon. In addition, I give the results which have been obtained from chemical and bacteriological analysis. The samples were taken on the day when M. Hermite explained his system on his recent visit to the town.

Chemical Analysis.

Three samples, collected on February 26, 1894, were sent to Dr. Dupré, F.R.S., of Westminster Hospital. They were from the following sources: (1) M. Hermite's solution, taken in yard A; (2) sea-water; (3) sewage effluent in yard C, after treatment with the electrolysed fluid. Each sample was sent in a Winchester quart bottle, sealed and stoppered. Dr. Dupré, in his report dated March 9, 1894, states as follows: "(1) M. Hermite's solution.—The water contains a small proportion of hypochlorite, probably magnesium or sodium, equal in effect to 0·72 gramme of chlorine per litre, or 50·4 grains per imperial gallon. The sample contained 1,315 grains of combined chlorine, equal to 2,167 grains of chloride of sodium per gallon. (2) Sea-water.—The sample of untreated sea-water sent contains no hypochlorite or free chlorine, and 1,315 grains of combined chlorine per gallon, which is about the normal amount in pure sea-water. The sewage is of dark-brown colour, and very turbid; it has no offensive sewage smell, but has a somewhat disagreeable beery smell. It still contains a small amount of hypochlorite. The amount of oxygen absorbed is extremely high, about four times as much as in the case of ordinary London sewage. The proportion of free ammonia is low for a sewage, but this may, however, be due to its being fresh. The amount of albumenoid ammonia yielded is extremely high. The sample of sewage is evidently of somewhat abnormal character, and does not seem very well suited

Digitized by Google

for experimental purposes. Without a direct comparison between the treated and untreated sewage, it is impossible to say what improvement the treatment has effected. I may say, however, that this sample does not smell like ordinary sewage, and has not developed an offensive sewage smell after a week's keeping. Judging from the amount of combined chlorine present, compared with that of sea-water, either a far smaller proportion of sea-water has been used for flushing than water in the case of ordinary water-closets, or else the sewage is otherwise mixed with much water."

ANALYTICAL DETAILS.

Appearance	Turbid, filthy looking.
Colour	Dark brown.
Smell	Not offensive, but somewhat beery smell.
Deposit	Much foul.
Nitrous acid	—
Phosphoric acid	—
Oxygen absorbed from permanganate.	20·3 grains per gallon.
Total dry residue	1,264·0 grains per gallon.
Colour of residue.....	Dark brown.
Behaviour of residue on ignition.	Much charring, evolves slight smell of urine and nitrogenous matter, also that of residue from beer.
Chlorine.....	538 0 grains per gallon.
Ammonia	·931 ,, ,,
Albumenoid ammonia...	2·45 ,, ,,
Hypochlorite equal to free chlorine.	0·026 ,, ,,

BACTERIOLOGICAL ANALYSIS.

Three samples, collected on February 26, 1894, were sent to Dr. Klein, F.R.S., of St. Bartholomew's Hospital. They were from the following sources: (A) Sewage effluent in yard C, after treatment with the electrolysed fluid; (B) sea-water; (C) M. Hermite's solution taken in yard A. Each sample was sent in a Winchester quart bottle, sealed and stoppered.

Dr. Klein, in his report dated March 5, 1894, states that "Sample A was a very turbid fluid, with a large amount of flocculent matter suspended in it; it had no offensive smell. Sample C was clear, and had a strong chlorine smell. Cultivations were at once made from the three samples: "Sample A.—(1) One plate was made with 1·0 c.c., and one plate with 0·1 c.c. of the fluid. (2) 500 c.c. were driven through a Berkefeld filter. This fluid took, owing to the very large amount of solid matter suspended in it, nearly an hour to pass through the filter; the same quantity of water would, as a rule, take about 10 minutes. The particulate matter of the outside of the filter was then brushed off, suspended in 10 c.c. of sterile water, and with 1 c.c. of this each of two gelatine tubes were charged and used for plate cultivation. Result: In both the plates of series 1—*i.e.*, charged with 0·1 c.c. and 1·0 c.c. of original fluid A—numbers of colonies of bacteria developed: an estimation of their number showed that fluid A contained per 1 c.c. between 800 and 1,000 living microbes. From the various colonies of these plates the following species have been isolated: (*a*) bacillus coli, very numerous, (*b*) bacillus subtillis, (*c*) proteus vulgaris, (*d*) bacillus ulna, (*e*) bacillus mesentericus, (*f*) a non-motile cylindrical bacillus, not liquefying, (*g*) various species of cocci. It follows from this that of the species that developed, several are such as do not form spores—*e.g.*, bacillus coli, proteus vulgaris, and the several species of cocci.

"In the plates of series 2—that is, those which each received the solid matter of 50 c.c. of the original fluid—the number of colonies that came up in 48 hours was so great, and the liquefaction so extensive, that they were practically useless for counting them or determining their character. Now this sample A, as far as I understand the description given on the label and in your letter, was sewage that had been subjected to the treatment after M. Hermite's process. Ordinary raw sewage of London, Manchester, and other towns that I have examined, contains between three millions and 10 millions of bacteria per c.c.; this 'treated' sewage effluent of Worthing, as stated above, contains only 800 to 1,000 microbes per 1 c.c.; it follows that there has been effected by the admixture of the Hermite solution a remarkable reduction in the number of living microbes, but it also follows that nothing like sterilisation has been produced, since a considerable number of bacteria have survived the process; and be it also noted that amongst those that survived are several species that do not form spores, so that an assertion to the effect that the highly-resisting spores are not killed, whereas non-sporing bacilli are killed by the process, is not borne out by these observations.

"A further experiment was made with this sample A on March 3—*i.e.*, after it had been kept four days. With ½ c.c. of the fluid A, a gelatine plate was made and the result watched. On the third and fourth day the number of colonies were counted, and as a result it was found that their number had increased meanwhile more than fourfold. Cultivations made after six days' keeping showed that the number of microbes had meanwhile increased more than one hundredfold. Sample B: A plate was made with 1 c.c. of this sea-water. The number of colonies that came up was too great to be counted; in fact, the gelatine was densely pervaded by colonies. A plate was made with 0·01 c.c. of the water, having been kept for two days. The number of colonies was estimated to be 1,000 per 1 c.c. Sample C was treated in the same manner as sample A. Result: The fluid proved sterile, only two colonies were noticed in one plate made with the particulate matter of 100 c.c. of the sample; the companion plate was free of any growth. Now, this result is extremely interesting, for it proves that sea-water containing a very large number of living microbes (sample B) becomes practically sterilised by the Hermite process (sample C).

"In order to ascertain further whether cultures of non-sporing bacilli when mixed with Hermite's solution become sterilised thereby, I made the following experiments; but I should repeat here that I had no great hopes after the results obtained with sample A, for we have seen that this sample was not anything like sterile, still containing 800 to 1,000 microbes per 1 c.c. Broth cultures of (1) bacillus coli, (2) bacillus of typhoid, and (3) cholera vibrios were mixed each with the same bulk of Hermite solution (C), and after thoroughly shaking were left standing for 20 minutes, and from them sub-cultures were made in normal nutritive media, in broth and in gelatine, each culture tube receiving one drop of the mixture. The result was this: All sub-cultures in broth showed growth, the broth cultures were uniformly turbid, in 24 hours incubated at 37deg. C.; the gelatine tubes of the bacillus coli and the cholera vibrio incubated at 20deg. C., showed numerous colonies after 48 hours, those of the typhoid developed a small number of colonies after four days. This is quite in harmony with the experience repeatedly made—viz., after allowing the disinfectant to act on the microbes, it is necessary to expose the sub-cultures made from the 'treated' material to 37deg. C., in order to avoid a hasty conclusion; repeatedly it has been found that while sub-cultures exposed to 20deg. C. failed to give a positive result in two days, those exposed to 37deg. C. yielded good growth. The growth which appeared in these different sub-cultures in broth was tested by further sub-cultures, and thereby it was ascertained that the same microbes that were used for the initial experiment were recovered in their perfectly normal characters. There is one point in connection with this series of experiments which is of importance, and that is—that by the addition of the same bulk of Hermite solution to the original normal cultures the number of living microbes had decidedly become reduced, although a good many living examples were still left. This was determined in the following manner: From the original normal cultures 1, 2, and 3, a definite quantity was withdrawn, mixed with the same bulk of sterile salt solution, and from this mixture plates in Agar were made and incubated at 37deg. C., in order to determine the number of microbes per 1 c.c. After the treatment of the original cultures with the same bulk of Hermite solution for 20 minutes, similar plates were made and the number of colonies coming up in these plates was compared with those of the previous control plates. It was found that by the Hermite solution the number of living microbes was reduced something like over 100 times.

"A further experiment was made with these broth cultures of colon, typhoid, and cholera, to which an equal bulk of Hermite solution had been added. It was this. After keeping the mixture for 24 hours, inoculation was made into fresh sterile broth, each tube receiving about five drops of the 'treated' culture. The result was interesting. The bacillus coli and cholera vibrio yielded normal growth; the typhoid did not yield any growth; so that even after 24 hours' exposure of broth culture of bacillus coli and of cholera vibrio to an equal bulk of Hermite's solution, each five drops of the coli fluid and the cholera fluid still contained living microbes, while the typhoid fluid appeared sterile.

"Now, it is maintained by the 'Hermite system,' as explained in the printed leaflet which you kindly sent me, that 'fæcal matter is instantaneously destroyed (meaning, of course, sterilised) when mixed with the electrolysed disinfecting liquid.' The above experiments show that this was not the case with the sewage operated upon at Worthing, nor was it the case when cultures of bacillus coli, bacillus of typhoid or of cholera vibrio, were subjected to the liquid. I do not know what is the proportion of Hermite solution that this 'Hermite system' recommends to be added to 'fæcal matter' in order to sterilise it, but it must be quite clear from the above experiments on the broth cultufes that even an equal bulk of Hermite solution added to the cultures does not by any means sterilise them even after 20 minutes' exposure, and some not even after 24 hours. Whether such an addition—*i.e.*, equal bulk—in regard to sewage is possible in practice, is a matter on which I do not wish to give an opinion, but anything equal, or *à fortiori* anything less, would for sterillisation purposes be vain. Of an 'instantaneous' action there is nothing to be noticed in the above experiments."

Since there is no instantaneous decomposition of fæcal matter and no sterilisation of sewage, I am of opinion that the process, as far as the late trials have gone, has therefore failed to produce the results which are claimed for it by its inventor.

THE COMMERCIAL POSITION OF ELECTRIC SUPPLY AND MANUFACTURING COMPANIES.*

It is now about a year ago since we reviewed the position of the electric lighting companies, and pointed out the fair promises for the future which many of them held out. The report of these companies for the past 12 months are now nearly all to hand, and in the vast majority of cases they amply justify the predictions which we ventured to make in the early part of last year. The capital embarked in this new-fangled business, which is mainly the growth of the last five or six years, is increasing annually. The 14 companies operating in London and its suburbs have now between them a paid-up share capital of £3,250,141, in addition to an issued loan capital of £604,600, so that together we have nearly four millions of money

* From the *Financial Times*.

Digitized by Google

embarked in the electrical supply business in the Metropolis alone. The provincial companies are generally on a smaller scale, but between them hold a considerable amount of capital; thus the paid-up share capital of 20 provincial companies amounts to £721,030, and the loan capital to £160,484. Then there are the manufacturing companies, nine of which have between them a paid-up share capital of £2,051,654, and have issued loans to the extent of £365,130. Taking all the large companies, supply and manufacturing, together, we find the total paid-up share and loan capital employed by them comes to £7,153,039. This is a respectable amount to have been absorbed in a few years by an entirely new industry, and fresh capital is constantly flowing in the same direction. Many of the provincial companies have not issued more than half or a third of their share capital, and one or two of the London companies are in a similar position, while others, whose share capital is all called up, now and then make a fresh issue of debentures. Not only, therefore, have we already a large financial stake in electricity, but we bid fair to have double or treble the amount in a few years' time. Electric lighting has spread slowly in the United Kingdom compared with its progress in America, and even in parts of the Continent, but our provincial towns are now taking the matter up one after the other, and the present year will probably see a great extension in this direction.

Considering the convenience, healthfulness, and beauty of the electric light, it is extremely satisfactory to find that, as far as can be judged from the history of the companies, it is undoubtedly a commercial success. Subjoined we give a table showing the results given by nine leading London supply companies for the past two years:

London supply companies.	Year ended.	Results as per Reports. Current sold, rents, fees, etc. £	Cost of current, management, etc. £	Profit or loss for year. £
Charing Cross and Strand..	Dec. '92	20,659	10,411	+ 10,248
	,, '93	22,304	13,650	+ 8,654
Chelsea	,, '92	12,523	8,204	+ 4,319
	,, '93	13,732	7,463	+ 6,269
City of London	,, '92	10,426	9,991	+ 435
	,, '93	40,032	23,092	+ 16,940
House to House	,, '92	10,689	7,852	+ 2,837
	,, '93	12,064	7,832	+ 4,231
London	,, '91	15,081	22,091	- 6,958
	,, '92	23,693	27,716	- 3,914
Metropolitan...	,, '91	43,747	34,028	+ 9,719
	,, '92	54,572	40,404	+ 14,168
St. James's and Pall Mall ...	,, '92	34,559	21,100	+ 13,459
	,, '93	21,059	21,149	+ 9,919
Westminster...	,, '92	36,443	24,834	+ 11,609
	,, '93	43,833	28,267	+ 15,566
Kensington ...	,, '92	17,539	10,711	+ 6,828
	,, '93	21,745	12,695	+ 9,050

In all except three of these nine companies we find an increase in profits for last year. In one instance, that of the London Company, which has not yet reached the dividend-paying stage, there is a diminution of nearly 50 per cent. in the amount of loss made. The Charing Cross and Strand and the Westminster Companies show exceptionally a decrease in profits, but this does not necessarily imply retrogression, for in each case there has been considerable additional expenditure on capital account, which has yet to be made productive, although it may be admitted that these companies have not done so well as the others on the list. But, taking the table through, it is fairly evident that there was last year a considerable increase in gross receipts, which, coupled with a diminution in the ratio of expenditure, has produced a most favourable effect upon net revenue. The results shown are the more satisfactory as we know that in one or two instances the companies have reduced the price of their current. That this tendency has not been confined to London alone is proved by the next table appended, showing the progress made by some of the provincial companies, which, generally speaking, are of later date than those of the Metropolis.

Provincial supply companies.	Year ended.	Results as per Reports. Current sold, rents, fees, etc. £	Cost of current, management, etc. £	Profit or loss for year. £
Birmingham ...	Dec. '92	—	—	+ 2,320
	,, '93	—	—	+ 3,124
Bournemouth .	,, '92	3,664	3,337	+ 327
	,, '93	5,222	3,740	+ 1,482
Eastbourne ...	,, '92	4,549	3,203	+ 1,346
	,, '93	5,216	3,235	+ 1,981
Liverpool	,, '92	—	—	+ 10,652
	,, '93	—	—	+ 11,410
Newcastle and District	,, '92	5,916	3,777	+ 2,139
	,, '93	7,221	4,271	+ 2,950
Newcastle-on-Tyne	,, '92	6,213	3,912	+ 2,300
	,, '93	6,753	4,293	+ 2,460
Northampton..	,, '92	1,229	922	+ 307
	,, '93	1,492	956	+ 536

In every one of these instances there is a fair increase on profits. The tendency here exhibited is general, and extends to other companies which are not tabulated on our list. Some companies, such as the Oxford and Hastings, have only been actually supplying current for a year, so that no comparison is possible, but they yet show a fair profit on working. Where the comparison, as in the case of one or two of the London undertakings, can be made for three years, the results obtained are similar.

The manufacturing companies do not exhibit the same progress, owing possibly to the fact that the great demand for the London area has for the time being relaxed. Of the four companies referred to in the annexed table, only one, the Edison and Swan, exhibits an increase in profits for its last fiscal year:

Manufacturing companies.	Year ended.	Results as per Reports. Sales, etc. £	Expend. £	Profit. £
Brush	June, '91	39,916	23,359	16,577
	,, '92	55,451	28,097	27,354
	,, '93	52,556	26,914	25,642
Crompton	March, '91	33,709	20,678	13,031
	,, '92	38,355	23,287	15,068
	,, '93	40,443	28,490	11,953
Edison and Swan	June, '91	146,699	73,794	72,905
	,, '92	152,740	77,927	74,811
	,, '93	195,046	108,403	86,643
Swan United...	Sept. '91	59,942	20,903	39,039
	,, '92	45,432	10,592	34,840
	,, '93	38,475	9,597	28,878

For much of the information conveyed in the above tables we are indebted to some very carefully-compiled statistics made by a well-known firm of Stock Exchange brokers. From an inspection of these statistics we come to the conclusion that the supply companies which display the most promise, as far as can be judged from past results, are the Chelsea, the House-to-House, the Westminster, the Liverpool, the Kensington and Knightsbridge, and possibly the City of London. The too hasty and lavish expenditure of capital is the great danger which has to be guarded against, and in this respect some of the provincial companies set a good example to their London contemporaries. Of the 33 supply companies enumerated in the statistics referred to, 11 have reached the dividend-paying stage, and five out of the 11 have declared their first dividend this year. As a whole, the outlook for the supply companies is distinctly hopeful, always provided that they take care not to rush too fast ahead in the matter of capital expenditure.

KINGSTON-UPON-HULL ELECTRIC LIGHTING ACCOUNTS.

The accounts of the electric lighting department of the Kingston-upon-Hull county borough for the year ending December 31, 1893, have just been issued. The capital expenditure during that year amounted to £21,637, and the total expenditure to December 31, 1893, has reached the sum of £32,818. We give below the revenue account and general balance-sheet:

REVENUE ACCOUNT.

Expenditure.	£ s. d.	£ s. d.
A.—To Generation of Electricity.		
Coal or other fuel, including dues, carriage, unloading, storing, and all expenses of placing the same on the works	£470 19 6	
Oil, waste, water, and engine-room stores	76 1 3	
Wages at generating stations	274 0 6	
Repairs and maintenance, as follows: engines and boilers, £31. 15s. 3d.; other machinery, instruments and tools, £2. 1s. 8d.; accumulators and accessories, £1. 5s. 6d.....	35 2 5	
		856 3 8
B.—To Distribution of Electricity.		
Wages and other remuneration to linesmen, fitters, labourers.....	68 14 5	
Repairs, maintenance, and renewals of mains of all classes, including materials and laying the same	14 10 11	
Repairs, maintenance, and renewals of apparatus at distributing stations	3 12 5	
		86 17 9
E.—Rents, Rates, and Taxes.		
Rents payable	111 19 7	
Rates and taxes	23 10 0	
		135 9 7
F.—Management Expenses.		
Salaries (engineer's department)	335 11 6	
Printing and stationery	103 15 10	
General establishment charges.....	91 4 6

COMPANIES' REPORTS.

SOUTHAMPTON ELECTRIC LIGHT AND POWER COMPANY, LIMITED.

Directors: Mr. G. T. Harper, chairman; Mr. W. H. Mitchell; Mr. J. F. Obree, vice-chairman; Mr. G. J. Tilling; Mr. J. F. Albright. Secretary: Mr. J. T. Hamilton.

Report of the directors and statement of accounts for the year ending December 31 last.

The anticipations of your directors of steady and continuous progress in the business of the Company have been realised. The increased revenue amounts to £553. 9s. 10d. over 1892, but a satisfactory feature is that the expenses are practically the same, thus making the whole of the increase net gain.

STATEMENT OF REVENUE AND EXPENSES.

	Lamps (8-c.p.), Dec. 31.	Units sold.	Revenue. £	s.	d.	Expenses. £	s.	d.
1891 (part only)	—	5,469	350	5	11	535	2	1
1892	2,200	35,537	1,153	4	10	1,152	0	4
1893	3,162	53,848	1,606	14	8	1,121	4	8

This statement is doubly gratifying inasmuch as the directors reduced the maximum price of the current to 8d. from January 1, 1893. With the view of placing the Company upon a dividend-paying footing, your directors have resolved to relinquish the fees already debited in the two previous balance-sheets—namely, £400—and to take no fees for the year 1893. After debiting interest on debentures and overdraft and depreciation, a net profit of £170. 1s. 11d. is shown. This sum, together with £400 recredited for directors' fees, reduces the loss brought forward of £754. 19s. 9d. to £184. 17s. 10d. As the sales of current for January and February of this year have shown an increase of 50 per cent. over the corresponding period of the previous year, your directors feel justified in expressing the opinion that they will be able to declare a dividend at their next annual meeting. To enable the directors to cope with the new applications, it is highly essential that more capital should be forthcoming, and in view of the favourable showing of the Company's working, the directors hope for the support of the shareholders in bringing fresh capital into the business. The directors who retire from office are Mr. J. F. Obree and Mr. G. J. Tilling, who, being eligible, offer themselves for re-election. The auditor, Mr. C. Cox, also offers himself for re-election.

COMPANIES' MEETINGS.

BOURNEMOUTH AND DISTRICT ELECTRIC SUPPLY COMPANY, LIMITED.

The third annual general meeting of the shareholders of the above Company was held on Friday last, Mr. Leveson Scarth occupying the chair. The report of the directors was as follows: "The directors beg to submit herewith a statement of accounts for the year ending December 31, 1893. The progress made by the Company during the past year has been very satisfactory. The number of lamps connected was equivalent on December 31, 1892, to 8,988 of 8 c.p.; and on December 31, 1893, to 14,552 of 8 c.p.—showing an increase of 5,564 during the year. At the date of this report the number of lamps connected is equivalent to 15,286 of 8 c.p. Many more are in course of installation, and will shortly be connected to the Company's mains. The accounts now submitted show a profit on the full year's working of £1,481. 10s. 6d., and after providing the sum of £444. 0s. 4d. to pay interest due to end of December last on the £10,000 6 per cent. first mortgage debentures so successfully issued in the spring, £32. 15s. 11d. standing at interest account, and writing off the balance of loss brought forward from 1892 (£34. 3s. 3d.), a net balance of £974. 16s. 9d. profit remains. Of this sum it has been decided to write off £615. 14s. 5d. to depreciation account, leaving a balance of £359. 3s. 4d. available for purposes of dividend. Considerable additions and extensions have been made to the buildings, machinery, plant, and mains, the latter item including the extension of the Company's system to Boscombe, where are supplied the Hotel Burlington (an equivalent of about 1,200 8-c.p. lamps) and the extensive block of buildings comprising the arcade, shops, and Salisbury Hotel, owned by Mr. Beckett. The plant of the lighting station has been found to be fully adequate to the demands made upon it, and on the Saturday before Christmas Day the heaviest load of the whole year (132 amperes) was successfully carried, extra engine and dynamo power being held in reserve sufficient for supplying current to about 3,000 lamps of 8 c.p. in addition. The electric light is finding increased favour throughout the extensive district covered by the Company's

Digitized by Google

mains. Fresh applications are continually being received, and the directors look forward with confidence to the result of the present year's working."

The **Chairman**, in the course of his remarks, stated that the business was progressing with reasonable rapidity, and had now reached the stage of being a dividend-earning concern, the directors having decided to recommend the payment out of profits of two-thirds of a 5 per cent. dividend on ordinary shares, the Brush Company paying the remaining one-third under their guarantee, which did not expire till June next. With regard to the items figured in the balance-sheet in respect to preliminary charges and telephone action, and to which the Company's auditors had called attention, the Board recommended that the £500 standing to credit as preliminary expenses be charged to capital account, but that the debenture preliminary expenses and the cost to the Company of the telephone action be dealt with, gradually writing off against revenue account a proportion year by year. The difficulties represented by the large sum cost of telephone action were, the directors hoped, nearly at an end, especially as the telephone company were now adopting the system of complete metallic circuits for their currents, a method which, supplementing the continued efforts of the Company, would obviate all future trouble. The directors had devoted much attention to mains and cables, and were incurring considerable expense in accelerating the policy of laying down concentric cables throughout the system. All the requirements of the Board of Trade were being promptly satisfied, and the directors wished to acknowledge the courtesy with which these necessary works were being facilitated by the Town Council and surveyor. The plant at the central station had been and was still fully adequate to the load, as stated in the report, but the directors anticipated an increase of at least 30 per cent. in the output during the ensuing year, and this would necessitate additional engines and alternators At the same time, they would endeavour to preserve the greatest economy in running expenses. During the last two months Mr. A. J. Lawson, M.I.E.E., London, had been acting as consulting engineer, and the directors, out of a large number of applications, appointed as resident engineer Mr. H. M. Sayers, engineer to the electric lighting company in Oporto. Mr. Sayers would take technical charge of the Company's system from April 20. Mr. Shepherd's connection with the Company, for which he had done much work since its formation, had now terminated. The directors looked forward with confidence to declaring a fair dividend out of the earnings of the Company during the present year.

The motion for the adoption of the report and accounts was seconded and carried.

The retiring directors, Mr. John Fair and Mr. William Fisher, were re-elected, and Messrs. Cridland and Co., the Company's auditors, were reappointed auditors to the Company.

BUSINESS NOTES.

Great Northern Telegraph Company.—For the month of March the receipts were £22,000.

Western and Brazilian Telegraph Company.—The receipts for the week ended March 30 were £2,659.

Sunderland.—The Sunderland Corporation is seeking sanction for a loan of £25,000 for electric lighting works.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 1st inst. amounted to £841.

Portsmouth.—The Corporation have this week invited applications for various positions in connection with the electricity supply station.

Direct Spanish Telegraph Company.—The receipts for the month of March were £215 less than for the corresponding period of 1893.

Cuba Submarine Telegraph Company.—For the month of March the receipts were £75 less than for the corresponding period of 1893.

Tenders for Rhyl.—Tenders are invited for the electric lighting of the Rhyl Pier and Pavilion. Applications to be sent to 3, Bradshaw-street, Shudehill.

Bradford-on-Avon.—The Town Commissioners have decided to consider the subject of electric lighting six weeks hence, and a deputation is to be invited to attend.

Kensington.—Messrs. Drake and Gorham have just been entrusted with the wiring of the two new houses in Melbury-road, Kensington. The number of lights will be 150.

The City of London Court.—The new wing which has been added to the City of London Court was formally opened on Monday. It will shortly be lighted by electricity.

Bath.—At a meeting of the Bath Town Council a proposal to connect the engineer's office by telephone with the works at Bathampton and Monkswood, at a yearly charge of £40 for 10 years, was adopted.

Issue of Debenture Stock.—The whole of the £30,000 4 per cent. debenture stock recently issued by the St. James's and Pall Mall Electric Light Company, Limited, has been applied for and allotted.

Personal.—The appointment of Mr. George G. Clark as second engineer in connection with the electric lighting station of the Aberdeen Town Council, for the period of six months, has been confirmed.

Eastern Telegraph Company.—The receipts for the month of March were £57,677, as against £55,786 for the corresponding period of 1893.

Direct United States Cable Company.—The Board have resolved to pay an interim dividend of 2s. per share, free of tax, being at the rate of 2 per cent. per annum, for the quarter ending March 31.

Globe Telegraph and Trust Company.—The directors have declared an interim dividend of 3s. per share, on the preference shares, less tax, and 2s. 6d. on the ordinary, from which the tax has already been deducted.

Dewsbury.—The Dewsbury Board of Guardians have decided to erect the buildings and plant for lighting the workhouse and cottage homes belonging to the union by electricity, and to ask for powers to borrow £2,150 towards the cost, the original estimate of which was £1,400.

Pembroke Dock.—Two dynamos, with which it is intended to light by electricity the ships building at the dockyard, have been ordered, and will be delivered shortly. The dynamos will also supply the current necessary for a new process of drilling which it is proposed to introduce.

City and South London Railway.—The receipts of the Company for the week ending April 1 were £844, against £744 for the same period last year, or an increase of £100. The total receipts for the first half-year of 1894 show an increase of £20 compared with those for the corresponding period of 1893.

Bristol.—At their meeting which was to be held yesterday the Sanitary Committee were to have before them the estimate for the forthcoming half-year, and among the items which do not promise to be less than in the corresponding half of last year is the call from the Electrical Committee. It amounts to something like £4,000.

Forthcoming Lectures at Sheffield.—A course of lectures will be given on April 9 and the two following Mondays, in the Central School, Sheffield, by Mr. T. Scott Anderson, A.M.I.E.E., in which will be covered the various means whereby electric power may be utilised in connection with welding, forging, hardening, tempering etc.

Is there a Market in Siberia?—Andreas Eltischeff, Jekaterinburg, Russia, importer for the Ural and Siberia of technical and electrical machinery, armatures, tools, and instruments for machines of every description, invites manufacturers desirous of introducing their goods to the Ural and Siberia to send him price lists and terms.

Dover.—The engineer and consulting engineer of the Dover Electric Light Company visited Dover last week and arranged for laying down the pipes for containing the mains which will be necessary for supplying public and private lights in Dover. Mr. H. Stiff, the contractor for the buildings, has commenced the erection of the station.

Larne.—At the monthly meeting of the Town Commissioners of Larne the draft contract between the Commissioners and Messrs. J. E. H. Gordon and Co., electrical engineers, for the lighting of the town, was submitted, and, after discussion of some amendments, it was agreed that it be forwarded to London for the approval of the contractors.

Tenders Invited.—The Committee of Visitors of the North Wales Counties Lunatic Asylum invite tenders for the construction and maintenance, for a period of five years, of a telephone between the asylum and Glanywern Hall, a distance of about three miles. Further particulars may be obtained of Mr. Wm. Barker, clerk to the Visitors, the Asylum, Denbigh.

W. T. Henley's Telegraph Works Company, Limited.—Warrants have been posted to the shareholders of this Company for dividends at the rate of 7 per cent. per annum on the preference shares (less income tax) for the half-year ending December 31, 1893, and 5 per cent. per annum on the ordinary shares (free of income tax) for the year ending December 31, 1893.

Llanelly.—The Local Board have received a communication from the Electrical Installation Company (in reply to a communication from the Board) that they hoped to complete the agreement to proceed with the electric lighting of Llanelly in a fortnight's time. The Board on Monday decided that as sufficient time had already be given, the agreement with the company should be terminated.

Newcastle Street-Lighting.—At a meeting of the Newcastle City Lighting Committee, the committee ordered that an electric light of 1,500 c.p. be placed at the corner of Shields-road, and one of 1,500 c.p. to be placed at the corner of the junction of Picton-place and Oxford-street, in New Bridge-street, near the Blyth and Tyne Railway Station, both electric lamps to come into operation on August 28.

Belfast.—A meeting of the Corporation in committee was held last week to consider the appointment of a resident engineer to take charge of the electricity works about to be established. There were, it appears, 59 candidates, and it was arranged that the Electric Lighting Committee should make a selection of half-a-dozen from this number, and submit them for final decision to another meeting of the Council.

Cardiff.—At a meeting of the Cardiff Technical Instruction Committee, held at the South Wales and Monmouthshire University College, Principal Jones stated that the engineering buildings were progressing satisfactorily, and that it had been promised that the workshop would be ready by the end of this month. Provision will be made for the exhibition and use of engines, dynamos, and other machinery.

Digitized by Google

Eastern Extension Company's Debentures.—The Eastern Extension, Australasia, and China Telegraph Company, Limited, give notice that various debentures were drawn by lot on April 2, 1894, at the offices of the Company, and that they will be paid off at par on July 2 next at Messrs. Barclay, Bevan, and Co., 54, Lombard-street, E.C.

Eastern Extension, Australasia, and China Telegraph Company.—The accounts of the Eastern Extension, Australasia, and China Telegraph Company to December 31 show, subject to audit, a balance of profit of £189,080 after payment of three interim dividends The directors propose to distribute the usual dividend of 5 per cent. for 1893, together with a bonus of 4s. per share, or 2 per cent., making a total distribution of 7 per cent. for the year.

Medical Battery Company, Limited.—Mr. Warley, deputy official receiver, presided on Tuesday at a meeting of the creditors of the Medical Battery Company, Limited, for the purpose of considering a draft scheme of reconstruction put forward by the debenture-holders, shareholders, and creditors of the Company. At the opening of the proceedings it was ruled that the meeting should be private, and it was stated that the scheme would be made public when complete and approved.

Elmore's Foreign Copper Company. — In the Chancery Division, Mr. Justice Vaughan Williams had before him on Wednesday the petition of General Sir R. J. Meade for the winding up of Elmore's Foreign and Colonial Copper Depositing Company, Limited. Counsel said that the petition came up on the last day of last sitting, and it stood over till now. In the interval the petitioner had died, and the executors had not proved the will, and under these circumstances it was asked that it should stand adjourned for a month. His Lordship assented.

Crystal "Star" Pendant.—Messrs. Faraday and Son have introduced under this title a fitting which is designed as an effective top light in high rooms. It is especially suited to hang to the finials or hammerbeams of large halls and dining-rooms, or in high conservatories. At a height of 12ft. or more, the light is so refracted and transmitted by the cut-glass facets and silvered reflector that it becomes a complete star in appearance, and, since it is placed so far above the line of horizontal vision, the full power of an unscreened electric light is made available without injury or annoyance to the eye.

Aberdeen.—The premises of Mr. George Souter, 45, St. Nicholas-street, have just been equipped with the electric light. The installation has been fitted up by Messrs. Shirras, Laing, and Co., under the superintendence of Mr. J. A. Linney. Incandescent lamps have been used throughout. At a meeting of the Works Committee of Aberdeen Harbour Board a report was submitted by Mr. Smith, engineer, with reference to proposed alterations at Regent Bridge and the erection of a new bridge. Mr. Smith suggests that the bridge should be opened and closed by an electric motor driven off the town mains.

Turret Lathes and Screw Machines.—A catalogue has reached us from Mr. H. F. L. Orcutt, of 145, Cannon-street, E C. (who represents in this country Messrs. L. Loewe and Co., of Berlin), concerning the company's turret lathes and screw machines. Those referred to in the list are the company's standard types of turret lathes and screw machines. Special attention is directed to one class of automatic screw machine, which makes screws or formed parts from the rod of either brass, iron, or steel, and from square, hexagon, or round stock. This machine is easily operated, and by improved mechanism the loss of time between the various operations is reduced to a minimum.

Telephone Company of Egypt.—The eleventh ordinary general meeting of this Company was held on Tuesday at the offices, 14, Austinfriars, E.C., under the presidency of General A. Fraser, C.B., who, in moving the adoption of the report and accounts, said the change of the Company's administration and agency from Alexandria to Cairo had been somewhat of a strain on their resources; but no doubt the expenses would be recouped in the current and following years. The directors recommended the payment of a dividend of 6 per cent. on the preferred shares, leaving, after devoting £69 to depreciation of stores, £1,948 to be carried forward. The motion was seconded by Mr. H. Grëwing, and carried.

Altrincham Electric Supply, Limited.—This Company has been registered with a capital of £50,000 in £1 shares, to take a transfer from the Manchester Edison-Swan Company, Limited, of a provisional order granted to them by the Board of Trade, authorising the supply of energy for public and private purposes within the Local Board districts of Altrincham and Bowdon, and to carry on the business of electrical engineers. The first signatories are: W. J. Crossley, Altrincham, Cheshire; C. C. Dunkerley, Dunham Massey, Cheshire; W. P. J. Fawcus, Portinscale Hale, Cheshire; H. T. Gaddum, Bowdon, Cheshire; W. O'Hanlon, Bowdon, Cheshire; W. Warburton, Bowdon, Cheshire; and W. A. Arnold, 5, Cross-street, Manchester.

Dundee.—At a meeting of the Works Committee of Dundee Police Commission a letter was read from the Board of Trade with reference to a complaint by Mr. F. Freedman, High-street, concerning certain electricity meters lately in use in his premises. Mr. Freedman had applied for the appointment of an inspector to examine the meters, and to this the Board of Trade agreed, stating that Major Cardew, the electrical adviser to the Department, would be happy to make the test in the event of the meters being forwarded to the laboratory at London. The Works Committee of the Commission acquiesced in this arrangement. They, however, stipulated that if the meters should be found correct so far as the consumer was concerned, Mr. Freedman should pay all expenses.

Edison Gower-Bell Telephone Company of Europe, Limited. The report of the directors adopted at a meeting of this Company held last week was as follows: "The directors beg to submit to the shareholders their report and the accounts of the Company for the year ending December 31, 1893, showing a balance to the credit of revenue account on that date of £120. 6s. 10d., which it is proposed to carry forward. The Telephone Company of Austria was placed in liquidation on February 16, 1893, but your directors do not anticipate that any return of capital will be received on the 1,000 ordinary shares held by this Company. The action against infringers in Belgium is now being argued before the Court of Appeal at Liège, and the solicitors give reason to hope for an early decision."

Electric Traction Company, Limited.—This Company has been registered with a capital of £300,000, divided into 29,880 ordinary shares of £10 each, and 1,200 deferred shares of €1 each. The objects are to enter into contracts for the construction, repair and maintenance of, and to construct, equip, and maintain any works, including railways and other roads or ways to be used for traction by electricity, steam or other power; bridges, subways, roads, wharves, quays, canals and docks, water and gas works, including the laying of pipes for distribution; buildings of any kind, telegraphs and systems of telephonic communication, or electric lighting; and to work and carry on under contract, or as owners or lessees, any electric or other railway or tramway, telephonic, telegraphic, or electric lighting system, or other like undertaking. The first signatories with one share each are: Edwin T. Botwright, Frank P. Shuckard, W. H. Adams, H. D. Brooke, W. Bryson Butler, W. Y. Yeoman, and Geo. Dewdney.

Anglo-Portuguese Telephone Company, Limited. — The directors' report presented at the seventh ordinary general meeting of the Company, held at the offices, 53, New Broad-street, E.C., on the 29th ult., stated that the amount to the credit of profit and loss account, after making all deductions, and including the balance brought from last year, was £6,171. 16s. 9d., which amount it was proposed to carry forward to the current year's accounts, the declaration of a dividend being, on the advice of the Company's solicitors, postponed for the present. The expenditure on capital account for the year amounted to £3,003. 11s. 1d. The number of paying subscribers at December 31 last was—in Lisbon 1,110, of a gross annual value of £8,295; and in Oporto 1,161, of a gross annual value of £6,436, making £14,731, and showing a total increase in subscribers of 80, and in value of £721, over the preceding year. The continuance of the high rate of exchange between the two countries had again entailed a very serious loss, amounting last year to £2 061. 4s. 11d., which has tended to cripple the available financial resources of the Company.

Maidstone.—At a meeting of the Local Board last week, Mr. Barker called attention to the conditions enumerated by Alderman Ellis upon which the transfer of the electric lighting order was to be made to a company, and he suggested that those conditions should be entered on the minutes as embodying the reasons why the majority voted for the transfer. Alderman Ellis said it was true that he quoted nine suggestions as to the terms upon which he thought the transfer of the order should take place, but they were suggestions only, and did not form part of his amendment on that occasion. The Mayor remarked that these suggestions would all come before the Electric Lighting Committee in preparing the scheme for a transfer. Mr. Barker said he thought that they ought to be entered on the records, because those suggestions really had the effect of carrying the vote for a transfer. Mr. Tootell pointed out that some of the opponents of the transfer on the last occasion said the terms alluded to could not possibly be carried out. The subject then dropped, on the understanding that Alderman Ellis's suggestions would come up for consideration in committee.

City Lighting.—At the meeting of the Commission of Sewers on Tuesday, Mr. Turner said he had a matter of emergency to bring forward—namely, a serious failure in the electric light in the City last week. Mr. Ross (assistant engineer) stated that on the subject of the failure he had received a report from the electric lighting company to the effect that it was due to a damaged and defective cable, which, however, was speedily repaired. Mr. Turner said he thought it was most unfortunate that the electric light was liable to serious failures, especially as the gas was being removed from the streets. He hoped the engineer would impress upon the company the necessity for preventing, if possible, such failures in the future. Mr. Turner also complained that the company monopolised the pavements and various open spaces in the City with their materials to such an extent as to become an absolute scandal. Mr. Deputy Bedford said he would like to know the difference between the cost of gas and electricity. Mr. Johnson remarked that he believed that the cost of cleaning the present gas standards was something like £1,500 a year. Mr. Ross replied that the gas standards had now been removed from the main thoroughfares.

Electrical Engineering in New Zealand.—We quote the following from the New Zealand *Insurance, Mining, and Finance Journal*: "The partners in the New Zealand Engineering and Electrical Company, of Castle-street, Dunedin, are Messrs. R. H. Postlethwaite and Thomas Stevenson, who have supplied most of the lighting installations in the Middle Island. A considerable number of sluicing claims have availed themselves of a light which in every way asserts its superiority over the best lights produced by combustion. At Roxburgh, St. Bathans, Round Hill, and, in fact, everywhere where sluicing is carried on by night as well as day, the arc light has been successfully installed, with much satisfaction to both workers and proprietors. In most claims one of the hands does the supervision, in addition to his ordinary work.

Digitized by Google

In the Otago installations the necessary power is usually obtained by means of a small Pelton wheel. At the Blue Spur, the electricity generated is used, in addition to its use for lighting the workings, for exploding the blasts required for breaking up the auriferous cement. The company are at present engaged in perfecting an invention for assisting the amalgamation of gold with mercury, by which it is believed that a long-desired means of saving the present immense loss of gold which is well known to occur in all gold mining will be obtained."

South Staffordshire Tramways Company.—A petition by shareholders for compulsorily winding up the South Staffordshire Tramways Company, Limited, came, on Wednesday, before Mr. Justice Vaughan Williams. The Company was incorporated by a special Act in 1889, its principal place of business being at Darlaston, Staffordshire. The capital of the Company was £86,580 preference capital and £129,650 ordinary stock. The petition alleged various fraudulent acts on the part of the directors, and misapplication of the Company's moneys; that improvident contracts had been entered into; that there were, in fact, only two directors, who did not constitute a quorum; that the meetings provided for by the statute had not been held, and that for the purposes of such meetings as had been held bogus shareholders had been created, and the *bonâ fide* shareholders had no opportunity of being heard; that the directors refused to call a meeting; and that the interests of the real shareholders were not safe in the hands of the present Board. The petitioners were holders of £50,000 worth of stock; the Company opposed, and were supported in opposition to the petition by holders of £48,000 worth. The Company was stated to be perfectly solvent, and objection was taken that the affidavits in support of the petition were not sufficient evidence to justify the grave charges made. The petition was directed to stand over till Wednesday next for the filing of further evidence.

Lighting of Cherryhinton.—A meeting was held last week at the offices of Lord John Russell and Co., St. Andrew's-street, Cambridge, to consider the advisability of forming a company for supplying the parish of Cherryhinton with electric light. Mr. C. Bland, who presided, said that if they had a company at once for the electric lighting of Cherryhinton, it would not have a gas company or any other company to oppose it. They knew Cherryhinton was a very important place, and was growing every day. It was estimated that an electric light station could be put down in working order for £4,000. It seemed to him to be a little company about to be established for the good of the parish. Lord Russell said they proposed at first to put down one boiler, one engine, and one dynamo. The whole of the plant and machinery, the building, the land, and the mains and transformers to the various houses, could be put down for between £2 500 and £3,000. Speaking of his own firm as contractors, he said they were willing to take about 50 per cent. of their contract in debentures. They would at present require a sum amounting to about £2,000 by subscription. Lord Russell, replying to questions by the Rev. Canon Beck, said they would be able to supply 500 lights with the sum he mentioned; that was as much as they could expect to have taken up in the first six months. The Chairman suggested that the meeting should be adjourned to see if they could get the funds, and to see if the proposed company would be a paying undertaking. After discussion, it was decided to adjourn the meeting, the Chairman, Mr. Clark, and Mr. Piper being chosen a committee to make enquiries.

The Blackpool Tenders.—The following is a list of the tenders received for lighting the United Methodist Free Church, Adelaide-street, by electricity:

Maunsell Mercier and Co., 5, Deansgate, Manchester (accepted)	£70	0	0
Briscoe and Shaw, 27, Preston-road, Blackburn	129	0	0
Scott and Mountain, Limited, Close Works, Newcastle-on-Tyne	118	0	0
J. McLellan, 37, North-gate, Blackburn	105	0	0
F. Stewart, Assembly Rooms-arcade, Blackpool	98	11	6
Corlett Electric Engineering Company, Robottom-square, Wigan	95	0	0
Fowler, Lancaster, and Co., Limited, Albert Works, Graham-street, Birmingham	87	10	0
W. J. Proctor, Duke-street, Nuneaton	87	9	6
Paterson and Cooper, Powsall-road, Dalston	87	0	0
E. Dewhurst, Talbot-chambers, Blackpool	79	15	0
Donnison and Parmiter, 10, Corporation-street, Manchester	77	10	0
T. H. Churton, 5, South-parade, Leeds	75	0	0
B. Verity and Sons, 29, Princess-street, Manchester	70	12	0
These tenders include electroliers.			
Edison, Swan, and Co., Temple-chambers, Brazennose-street, Manchester	57	10	0
Bowker Bros., St. Paul's-road, Preston	53	0	0
Crabtree and Harrison, Back Church-street, Blackpool	53	0	0
W. Banks and Co., 32, Corporation-street, Bolton	45	0	0
J. Berry, 93A, Fishergate, Preston	42	12	6
Furnis, Paterson, and Co., 85, Malcom-street, Heaton, Newcastle	38	0	0
Baxendale and Co., Miller-street, Manchester	55	0	0
These tenders do not include electroliers.			

Electric Lighting of Guildford.—At a meeting of the Town Council last week, the Town Clerk said that he had received a letter from the Board of Trade, which stated that with reference to the previous correspondence on the subject of the application by the Holloway Electricity Supply Company for an electric lighting order for Guildford, they (the Board of Trade), before coming to a decision in the matter, proposed to give the Corporation and the promoters an opportunity of placing their views before the Board of Trade. They had fixed the hour of 11.30 on March 31 for the meeting, and requested representatives of the Corporation to attend. The town clerk read a copy of the objections which were originally forwarded to the Board of Trade, dated January 12. It was therein stated that the Corporation gave their consent to the granting of the provisional order on condition that it gave them power to purchase within six months after the expiration of 10 years, and any six months after the expiration of any subsequent period of five years, under the second section of the Electric Light Act, 1888. They also stated in their objections that they had recently purchased the town mills, and that a report they had received from their engineer pointed out that the surplus water power there, after utilising what they required for pumping purposes in connection with their water supply, might be advantageously used in connection with the electric lighting of the town, and the Corporation had it under their consideration whether they would themselves take steps with regard to the provision of electric lighting for the town. Councillor Salsbury moved, "That the Mayor and town clerk may represent to the Board of Trade that the Council are prepared to take steps to carry out the lighting of the town by electricity at the end of five years." Alderman Carling seconded the motion. After further discussion the motion was put, and lost by seven votes to five. It was unanimously agreed that the Mayor and town clerk should represent the Council before the Board of Trade.

Cooking by Electricity.—A correspondent of the *Pall Mall Gazette* writes to that paper as follows: "An account of an interview at the Patent Office, published in the *Pall Mall Gazette* of Friday last, speaks of cooking by electricity merely as 'practicable.' It may interest readers of the article to know that in the United States it is an accomplished fact. At the Chicago Exposition a large space on the southern gallery of Electricity Building was occupied by a complete electric kitchen, where every day a culinary artist was busily engaged. The firm that made the exhibit at Chicago had as their motto the significant words, 'You push the button; we do the rest,' and in a prospectus they summed up the advantages of the system under 15 heads. The all-important questions of safety and cost remain to be dealt with. At Chicago I handled the wires in the electric kitchen again and again, and by taking pains to secure actual contact at two points, experienced the full shock of the current, which was nothing more serious than might have been caused by the slightest pressure of a pin point. The cooking apparatus can be brought into use wherever there is a circuit, arc or incandescent. The ordinary electric light fittings may be utilised; thus when the flatiron was shown in operation at the World's Fair, the globe of an incandescent lamp was simply screwed off, and the wire connected with the iron fixed in its place. Next, as to cost. I tried to get exact figures, and was assured by the representative of the firm exhibiting at Chicago that electric heat for the cooking, washing, and ironing of a family of six persons can be supplied in most American towns for 5dol., or £1 per month—that is, £12 per annum. If this estimate be correct, it is safe to predict that gas stoves and coal-ovens will, at least in America, be knocked out of existence for domestic cooking in 10 years' time. No coal, no wood, not even a match for kindling; no ashes, no smoke, no dust, no labour, no odour, no danger; no heat but what is actually utilised, and, consequently, no waste. These form a category of negative points of advantage that cannot be approached by any other form of cooking apparatus."

Claim for Electric Batteries.—In the Westminster County Court on Wednesday, the case of the Maquay Electric Light Company *v.* Wild was tried before his Honour Judge Lumley Smith, Q.C., and was an action by the plaintiff company to receive payment in respect of a quantity of batteries and electric light fittings alleged to have been supplied to the order of the defendant. Mr. Chilcott, solicitor, appeared for the plaintiff company, and said it would not be disputed that the goods were ordered and delivered, but he believed the defendant was going to say that he only gave the order on behalf of his brother, for whom he was acting as agent. The plaintiffs, however, would entirely deny that any such arrangement was even suggested. The Managing Director of the company was called, and said the order was received from the defendant in the ordinary way of business, and he asked that the goods should be delivered to his brother at Blackwall. Not the faintest suggestion was ever made to the effect that the goods were ordered on behalf of the brother, and he was never looked to for payment. A great many applications had been made to the defendant for payment, but he took no notice of them, neither did he ever take the trouble to dispute his liability until he was served with the summons in this action. He had been supplied with goods on previous occasions and had paid for them without any trouble. For the defence Mr. Wild was called, and admitted giving the orders for the goods, but contended that when he did so he made it perfectly clear to the plaintiff that he was acting as the agent of his brother, and that the latter would pay for them in due course. He had purchased goods from the plaintiff on many previous occasions, and had always paid for them, but in this instance he never undertook any liability in the matter. In giving judgment his Honour said that the man who gave an order for goods would in ordinary course be presumed to pay for them, unless he made it clear to the seller that he was acting as agent on behalf of another party. In this case he (the judge) was by no means satisfied that the defendant gave the plaintiff to understand that he was giving the order on behalf of another person. Judgment, therefore, would be for the plaintiffs for the amount claimed, with costs.

Result of Hanley Tenders.—The following is a list of the tenders received for the electric light wiring and fittings to the Corporation buildings—namely: (1) Town Hall, including Victoria

Digitized by Google

Hall; (2) Free Library and Boys' Reading-room; (3) Museum and Technical Schools; (4) Baths; (5) Market Hall and Fish Market; (6) Butchers' Market; (7) Electricity Works—for the Corporation of Hanley. Mr. Joseph Lobley is the borough engineer and surveyor.

C. A. Hemingway, Richmond	£5,681
Crompton and Co., London	4,925
H. South, London	—
C. Smith and Sons, Birmingham	4,159
J. Blackburn, Nottingham	—
Laing, Wharton, and Down, London	4,152
A. H. Wood, London	4,121
E. M. Evans, Manchester	4,086

J. D. F. Andrews and Co. (to different specification)	3,047
Spagnoletti and Crookes, London (accepted)	3,034

Where no amounts are entered tenders were sent for some of the buildings only.

Electric Light in Edinburgh.—A meeting of the proprietors and tenants of property situated in George-street, St. Andrew-square, Charlotte-square, and the streets leading into these thoroughfares from Princes-street was held in Edinburgh on Tuesday in support of the movement to have these streets included in the scheme of electric lighting. Sir Thomas Clark was called to the chair, and in explaining the object of the meeting he said they were met to protest against the action of the committee of the Town Council in excluding these streets from the electric lighting scheme. George-street and St. Andrew-square were originally included in the scheme, and it seemed extraordinary that perhaps the most highly-rated parts of the city were to have no benefit from the electric light. Mr. Macmillan urged that the Town Council, in carrying out their scheme, should give effect to the recommendation of Prof. Kennedy and lay down conductors sufficient for all the purposes that might be required, so that the streets might not be opened up again. Councillor Mackenzie, convener of the Electric Lighting Committee, said he came there to afford any necessary information, and he was not to be looked upon in the meantime as taking any side in the matter. Prof. Kennedy's original scheme included George-street and St. Andrew-square, and he said it would require 1,300 lamps. That proposal was remitted to the Cleaning and Lighting Committee, and at one fell swoop they blotted out the whole scheme of Prof. Kennedy and scheduled certain streets—this new arrangement necessitating 30 lamps more than Prof. Kennedy had estimated. That scheme was adopted by the Town Council. Then other streets were added, including the Canongate and High-street, which brought up the number to 175 lamps. That was the position so far as the Town Council was concerned. Prof. Kennedy was going to light from a continuous-current cable, and if it were decided to light George-street, he would do it through that cable, so that all that would be required would be to join the wires from the arc lamps. To light George-street, Charlotte-square, and St. Andrew-square would require 60 lamps, and the cost would be £20 per lamp, which would represent £1,200, and from that they had to deduct £400 as the price that would be saved from the lighting of these streets with gas. A committee was appointed to arrange for a deputation to lay the matter before the Town Council at their next meeting. The Chairman said that if they should be defeated in their efforts on this occasion to influence the Town Council, he was not quite sure that they would not have to make a representation on the subject to the Board of Trade. At a meeting of the Edinburgh Town Council, held on the same day, the following motion was passed: "That it be remitted to the Lord Provost's Committee to erect any spare lamps left over of the 175 sanctioned by the Council, after the streets already arranged for are supplied, in Fountainbridge, west ward from Earl Grey-street."

Dublin.—At a meeting on Monday of the Corporation, Mr. J. L. Robinson moved the adoption of a report of the Electric Lighting Committee regarding the extension of the electric lighting plant. He said that tenders had been asked from Messrs. Fowler and Co, Leeds, and also from Messrs. Porte, Sykes, and Co. for the supply of some plant, and the contract was given to Messrs. Fowler and Co., Leeds, and that firm had promised to give as much of the work as possible to Dublin. Alderman Toole seconded the motion. Mr. Buckley said there was a second report in connection with the matter, and he moved the postponement of the present one until the second report came up. Alderman Pile moved that the report be referred back to the committee for further information and comparison, and that all contractors who have already tendered get the same information and specification as Messrs. Fowler and Co. Mr. Clancy seconded the amendment. Mr. Robinson did not think it would be right to send the report back to the committee. They had obtained the advice of skilled men in the matter, and they were anxious to have the plant running in September. He said the tender of Messrs. Fowler and Co. was the best one. The idea was to have as much of the work as possible done in Dublin, and they asked them to have the boilers made in Dublin. They said that would increase the estimate by £200. Mr. Clancy enquired whether they had asked Messrs. Porte, Sykes, and Co. the same question. There appeared to have been correspondence with one firm to the detriment of another. Mr. Robinson said the tender of Messrs. Porte, Sykes, and Co. was unsatisfactory. They took up the most satisfactory one and entered into negotiations with the firm. Mr. Lenehan was of opinion that the report ought to go back to the committee for a more satisfactory report. Mr. Clancy said he thought there was a good deal more wrong in the electric department than had come under the notice of the public, and he would move that the Electric Committee be amalgamated with the General Lighting Committee, so that they would have more members of the Corporation acquainted with the matter together. Alderman Meade thought the amendment would mean sending to every contractor who had already tendered and asking for new tenders. Alderman Toole said if they had any belief in their engineers and surveyors, they had no alternative but to take their advice. The Lord Mayor said if they adopted the amendment in its present shape they would impose an enormous difficulty in the way of carrying out the electric lighting, and he was sure that was not the intention of Alderman Pile. Tenders were received from various firms, and Messrs. Fowler's tender was accepted. It required improvement in certain points, and the committee asked them to improve it and to get Irish manufacture where possible, and Messrs. Fowler and Co. agreed to that. The committee had decided before opening up further communication with that firm to accept their tender. The amendment was then put, and lost by 20 votes to 18. Mr. John Reilly moved a further amendment to the effect that the report be sent back to the committee for further information simply. Mr. M'Auley seconded the amendment, which was carried.

Eight-Hours' Day in the Engineering Trade.—Mr. W. Mather, M.P., has made public the report of the year's trial by Messrs. Mather and Platt, Limited, at the Salford Ironworks, Manchester, of the 48-hours' week. It states that the full complement of men at the Salford Ironworks is 1,200, though the actual number employed at any given date necessarily varies according to the state of trade. The trades represented at the works are patternmakers, moulders (iron and brass), smiths, coppersmiths and tinplate workers, engine fitters, millwrights, electrical mechanics, turners and fitters, brass finishers, boilermakers, planers, drillers, borers, machine tool men, and labourers. The character of the work turned out during the year of trial was similar to that of the preceding six years—namely, general engineering work. The year's trial was made during a period of general trade depression. The piecework system received a thorough representation in the trial, as well as the fixed weekly wage system. No overtime whatever was worked, except for breakdowns and repairs. The period of the experiment was comprised in the 12 months commencing March 1 and terminating February 28, 1894. On making up the books it was found that, comparing the ratio of wages to turn-over in the trial year with the ratio of turn-over in the six preceding years, there was an increase of 0·4 per cent. in the former. Had prices ruled the same, the turn-over in the trial year would, however, have been greater, and the wages cost, instead of showing an increase of 0·4 per cent., would have shown a decided decrease. The firm had found a marked economy in gas and electric lighting, wear and tear of machinery, engines, gearing, etc., fuel and lubricants, and miscellaneous stores. In regard to the increased fixed charges the balance was in favour of the trial year. The credit from these items to be carried to the trial year was an amount equal to 0·4 per cent. on the net amount of the year's turn-over. Thus, by a coincidence, a saving of 0·4 per cent. was secured as a direct consequence of the shorter hours, which counterbalanced the debit of 0·4 per cent. in the increased wages cost. A curious fact was illustrated by the pieceworkers' statistics. The diminution in their total wages meant a proportionately less production in actual work turned out by them. But as the total output of the works during the trial year was greater than that of previous years, the diminution in the production of the pieceworkers must have been more than compensated for by extra production on the part of the day-workers. The report concludes with the following observations: "We have now an opportunity of showing the workpeople and employers in other industries how beneficial changes may be made by mutual arrangement instead of by rigid legal enactments. There is no doubt that the results obtained at the Salford Ironworks, together with those at other places, demonstrate that the two morning hours before breakfast are not worth the pains and trouble they cost, whether to workpeople or to employers. The effect on the workpeople must be most damaging both physically and mentally; otherwise we cannot account for the remarkable and indisputable fact that when these hours were struck off, as much work was performed, all the year round, as when these hours were employed. My observations and the careful supervision of our foremen have not detected that our workpeople have consciously made anything like a spurt in the trial year, hoping thereby to gain a permanent reduction of hours, with the intention of easing off afterwards, as some have thought would be the case.

Digitized by Google

I attribute the full maintenance of our production through the trial year solely to the unimpaired and cheerful energy on the part of every man and boy throughout the day. . . . Our year's trial has convinced us that we have found the happy medium in the number of hours during which only one meal and one stoppage are needed, and this resolves itself into the eight-hours' day, or 48-hours' week."

The Electric Light Question at Bedford.—On the 30th ult., three deputations appeared before the Board of Trade, at the Whitehall-gardens, to urge their respective views as to who were the proper parties to supply the borough of Bedford with electricity. The Corporation were represented by counsel, Mr. Coward being instructed by Mr. T. S. Porter and Mr. Warwick Wade, solicitors. Mr. Sydney Morse, parliamentary agent for the Bedford Electric Lighting Company, was supported by Sir Henry Mance (chairman of the company), Mr. R. B. Stafford, Aldermen Haynes and L. Jessopp, Councillors J. Miller, C. Verey, C. D. Shelton, and Mr. W. B. Jessopp, who instructed Mr. Morse. Messrs. W. Roff, J. Harris, R. Hockliffe, R. P. Jarvis, H. Young, and W. E. Taylor were also members of the Ratepayers' Committee which had been formed to prevent, if possible, the provisional order held by the Corporation from lapsing into the hands of a company. After hearing the arguments adduced on each side, Sir Courtenay Boyle said: "This matter has been going on for a very long time. It is quite clear that there is not, at any rate, a consensus of opinion in Bedford as to what is best to be done. I think this is one of the cases where it would be better that the decision of the Board of Trade should be communicated at once. Therefore I am in a position to state to you what the advice will be that we shall give to Mr. Mundella, and if Mr. Mundella concurs, that will be the decision of the Board. I quite agree with Mr. Taylor that the primary interests that will have to be consulted are the interests of the ratepayers. The Board of Trade are glad to develop trade, and facilitate the efforts of such companies as Mr. Morse represents, but the principal parties to be considered by the Board of Trade are the ratepayers. Now we feel that in order to get at the views of the ratepayers of the borough of Bedford, the first persons we ought to consult are the Corporation, and we have the firmest possible reliance in the wisdom and discretion of the Corporation. But the Corporation have had an electric lighting order since August 4, 1890, and not done anything under that order at present, except to give to the difficulties of the situation their careful consideration. The time must come when consideration is not sufficient, and some definite action must be taken, and it seems as if the time has now arrived when, in the interests of a large section of the ratepayers of Bedford, some definite steps should be taken. If the Corporation will act upon their order, and will undertake to do something to show that they really intend to carry out their powers, the Board of Trade will be very loth to interfere with those powers. Therefore, this will be my first advice to Mr. Mundella. If the Corporation will, as soon as they can, pass the necessary resolution to supply electricity within the compulsory area proposed in the company's order, their assent will not be dispensed with and their order will stand, but if they will not so resolve, their consent will be dispensed with, and an order will be granted to a company. The ratepayers' interests will be safeguarded, because the Corporation's order will not be at once revoked. The compulsory area will be open to reconsideration, so that if the company get the advantages for which they contend they shall be liable to supply at once, or within the compulsory time, a rather more extended area than has been suggested. Something has been said about the position of the company. I have nothing whatever before me to lead me to infer that the company will not be able to satisfy the Board of Trade as to their ability. If the company do not satisfy the Board of Trade within six months as to their ability to carry out their powers in the compulsory area within the limited time, or if they do not conform to the terms as to the compulsory area, their order will be revoked. There is now an opportunity given to the Corporation to decide aye or no whether they will do something or agree together on doing nothing. If they do something their powers will stand, but if they do nothing they will forfeit their powers." The following is the text of order since forwarded by the Board of Trade: "If the Corporation will at once resolve to carry out supply in company's compulsory area before January 1, 1895, Corporation order will stand and their assent will not be dispensed with. If not, assent will be dispensed with, and order granted to company. But (1) Corporation order will not be revoked; (2) compulsion area will be open to consideration; (3) unless company satisfy Board of Trade within six months as to their ability to carry out their powers, their order will be revoked, or if they do not comply with the terms of the order. In such case the Corporation order will remain. If they do satisfy and do carry out, order of Corporation will be revoked."

PROVISIONAL PATENTS, 1894.

MARCH 27.

6212. **Improvements in and relating to conduits for electric railways.** Michel Angelo Cattori, 45, Southampton-buildings, Chancery-lane, London. (Complete specification.)

6218. **Improvements in or relating to electric keyboards for type-writing and type-setting machines and the like, also applicable for circuit-closing devices.** William Phillips Thompson, 6, Lord-street, Liverpool. (Charles Elmer Allen, United States.) (Complete specification.)

MARCH 28.

6241. **A method of depositing and affixing metals by electricity upon a medium which is fastened upon ceramic objects by burning in a kiln.** Frederick Alfred Rhead and Harry George Coleman, 6, Bath-street, Stoke-on-Trent.

MARCH 29.

6315. **An improved rotary electrical differential controlling device.** Alfred Lyster Shepard, 8, West Kensington-gardens, London.

6323. **Improvements in or relating to alternating-current apparatus or circuits.** William Morris Mordey, 46, Lincoln's-inn-fields, London.

6328. **Improvements in electric battery apparatus.** Jacob Ayton Archer, 55, Chancery-lane, London.

MARCH 30.

6366. **Improvements in electric arc lamps.** Ellis Vinson Cooke, Winton Ironworks, Patricroft, Lancs.

6368. **An improved apparatus for tightening telegraph wires and the like.** Edwin Alfred Hoad and Peter Simon, 5, Laurence Pountney-hill, London.

6396. **Improvements in and relating to ships' telegraphs.** Edward John Griffin and James Macnab, 96, Buchanan-street, Glasgow.

6402. **Improvements in electric accumulators.** George Edward Barker Pritchett, Theodore William Pritchett, and Archibald Gilbey Gold, 31, Soho-square, London.

6417. **Improvements in connection with switches for electric current transformers.** Albert Essinger and Thomas Harden, 55, Chancery-lane, London.

MARCH 31.

6458. **Improvements in dynamo-electric machines.** Sebastian Ziani de Ferranti, 27, Charterhouse-street, London.

6482. **Improvements in or relating to multiple telephonic systems and apparatus.** Prosper Moreau and Joseph Munier, 323, High Holborn, London. (Complete specification.)

6491. **Improvements in and apparatus for converting electric currents.** Sydney Pitt, 24, Southampton-buildings, Chancery-lane London. (André Blondel and Sautter, Harlé, et Cie., France.) (Complete specification.)

6495. **A process for protecting iron pipes from corrosion by passage of electrolysed chloride solutions employed as disinfectants.** Eugene Hermite, Edward James Paterson, and Charles Friend Cooper, 28, Southampton-buildings, Chancery-lane, London.

6497. **Improvements in apparatus for electrolysing chloride solutions employed for disinfecting.** Eugene Hermite, Edward James Paterson, and Charles Friend Cooper, 28, Southampton-buildings, Chancery-lane, London.

SPECIFICATIONS PUBLISHED.

1893.

4874. **Transforming, etc., electric currents.** Foster.
5198. **Electrolytic apparatus.** Hargreaves and Bird.
6684. **Gas, electric, etc., lamps.** Müller and Adkins.
7266. **Distributing electric energy.** Whitcher.
7713. **Gland joint for electric conductors.** Johnson.
8316. **Electrical propulsion of boats and vessels.** New and Mayne.
10584. **Electrolytic apparatus.** Castner.

1894.

2203. **Electric candle lamps.** Durlacher and others.
2514. **Electric bells.** West.
2562. **Electric tramways and railways.** Ashley.
2812. **Generating electric currents.** Tesla.
2900. **Electro-deposition of metals.** Rudholzner.
3223. **Heating gases by electricity.** Donaldson.

NOTES.

Havre.—The Havre Municipality propose to introduce the electric light into the local hospitals.

Rodez.—A company is being formed to supply this little French town with the electric light.

Rouen.—An application is being made for a concession for four electric tramway lines in this town.

Avallon.—M. Judic has applied to the local authorities for powers to supply the electric light to this town.

Bombay.—The premises of the Royal Bombay Yacht Club have been lighted electrically by Mr. A. A. Crawford.

Society of Arts.—On Monday, at 8 p.m., the third Cantor lecture on "Photometry," by Captain W. De W. Abney, C.B., F.R.S., will be delivered.

Many Customers.—The City of London Electric Light Company have now the names of 1,602 customers on their books, representing 85,757 8-c.p. lamps.

Sherborne.—The boys at Greenhill, Sherborne, have been amusing themselves in the way of imaginary football with the beam of light projected from a search-light.

The Charing Cross-Hampstead Railway.—The Charing Cross, Euston, and Hampstead Railway Bill was read a second time in the House of Commons on Wednesday.

Wiesbaden.—The authorities have approved of a scheme for the construction of an electric tramway, and for the conversion of the steam line into an electric tramway.

Glasgow University.—The Cleland gold medal for the best essay on "The Relation between Measurements of Electrostatic and Electromagnetic Units," has been awarded to Mr. Adam B. Stewart.

The Blackpool Electric Tramway.—The work of remodelling this tramway and the electrical plant is now proceeding, and it is expected that the line will be again set in operation in about six weeks.

Islington.—The Finance Committee of the London County Council reported on Tuesday that the loan of £9,000 to the Islington Vestry for the purchase of site for electric lighting station has been completed.

Nuremborg.—The Street Tramway Company are now waiting the approval of the municipal authorities for the use of electric power on their lines. The contract is to be given to the General Electricity Company of Berlin.

International Railway Congress.—At the International Railway Congress to be held in June next year, under Section II., "Locomotives and Rolling-stock," the general question of electric traction will be considered.

The Tesla Polyphase Patents.—An action has been brought by the Westinghouse Electric and Manufacturing Company against the General Electric Company for alleged infringement of the Tesla polyphase patents.

New Brunswick.—A telegram from St. John, New Brunswick, states that the Consolidated Electric Railway Company has been sold by auction for 92,000dol. Mr E. C. Jones, the manager of the Montreal Bank, is the purchaser.

Students of the Institution.—A students' meeting of the Institution of Electrical Engineers will be held at 28, Victoria-street, S.W., on Friday next, the 20th inst. A paper on "Secondary Batteries," by Mr. G. C. Allingham, will be read.

Lighting in the City.—The City of London Electric Lighting Company, Limited, are now prepared to supply current in no less than 406 streets, courts, lanes, etc. Current will be available in most of the remaining streets in the City by the end of May.

Appointment.—Mr. W. E. Clarke has been appointed assistant electrical engineer at the *Daily News* electric light installation. He qualified himself for the appointment under Mr. Ronald A. Scott, M.I.E.E., Acton Hill Electrical Engineering Works, London, W.

Fire.—We regret to learn that a fire broke out on Wednesday evening at the works of the Fowler-Waring Cables Company, Henley-road, North Woolwich. A building of one floor, 100ft. by 15ft. in dimensions, was destroyed and much damage was done to a larger building of two floors.

Pumping by Electricity.—A daily paper a few days ago described the passenger lifts at the north tower of the Crystal Palace. The water for the tanks is pumped to the top of the tower by two 6-h.p. electric motors, the current being obtained from the mains of the Crystal Palace District Electric Supply Company.

Iron and Steel Institute.—The annual meeting of this institute will take place at 25, Great George-street, Westminster, on Wednesday and Thursday, May 2 and 3. Among the papers down for reading is one by Mr. D. Selby Bigge, "On the Application of Electricity as a Motive Power in the Iron and Steel Industries."

The Telegraph Service.—A Treasury return shows that the total receipts of the Post Office Telegraph Service in the year 1893 amounted to £2,526,312, the total expenditure having been £166,682 more than that amount. The total balance of expenditure over receipts since the transfer of the telegraph service to the State is £509,706.

Lectures.—A lecture on "Michael Faraday" was delivered by Mr. J. W. Leyshon last week at Cardiff. Mr. T. Scott Anderson, master of electrical engineering in connection with the Sheffield School Board, has arranged to give in the Central Higher School, Sheffield, three lectures on electrical engineering. The first was delivered a few evenings ago.

Personal.—Mr. Walter G. McMillan, F.C.S., F.I.C., has been elected lecturer on metallurgy at Mason College. He is the author of a treatise on "Electro-Metallurgy," in Messrs. Griffin's "Scientific Text-Book" series. Mr. A. J. Lawson, M.Inst.E.E., has been appointed engineer and manager of the County of London and Brush Provincial Electric Lighting Company.

The South Staffordshire Electric Tramway.—We understand that the working of this tramway continues satisfactory, both from a financial and public point of view. Mr. Alfred Dickinson, the general manager and engineer to the company, will probably read a paper shortly on electric traction before the Institution of Civil Engineers, with special reference to this line.

Effect of Heavy Gases in Lamps.—At the recent meeting of the American Institution of Electrical Engineers, Prof. W. A. Anthony read a paper on the "Effect of Heavy Gases in the Chamber of an Incandescent Lamp." The author maintained that the use of bromine vapour in the chamber prevents blackening and maintains the candle-power and efficiency more uniform.

Electrical Exhibition at Budapost.—In our last issue reference was made to this forthcoming exhibition. We now note that the Department of Science and Art has received through the Foreign Office a despatch from her Majesty's Consul-General at Budapest calling attention to this exhibition of electrical machine tools which is to be held there from May 27 to September 30 next.

Digitized by Google

Lighting at Cardiff.—Considerable progress has been made in laying down the electric light plant. At the generating station the boilers are all in position, and the condensing plant has been put in. The engines are expected this week. With respect to the work in the town, very nearly all the pipe-laying has been accomplished, and nearly all the cables are in. The engineers expect that the whole of the work will be completed by July.

Units and Standards.—The American Institute of Electrical Engineers have approved the report of the Committee on Units and Standards recommending the provisional adoption of the term "gilbert" for the C.G.S. unit of magneto-motive force, the "weber" for the C.G.S. magnetic unit of flux, the "oersted" for the C.G.S. unit of reluctance, and the "gauss" for the unit of flux density.

Lighting in Sheffield.—The Sheffield Electric Light and Power Company, whose new station we described a few weeks ago, are inviting applications for a new issue of 6,000 shares of £7 each, making a total subscribed capital of £70,000, divided into 10,000 shares of £7 each. The increased share capital is required in order that the company may extend their mains into the residential districts of Ranmoor and Broomhill.

The £10,000 Prize.—It is stated that the Metropolitan Traction Company put into force the original time limit and withdrew its offer of a £10,000 prize on March 1. The reason assigned for not extending the time was that the State Railroad Commission had not accepted its offer to act as a referee. An American daily paper states that over 1,500 plans were submitted in competition. The Lawrence Electric Company, of New York City, has, however, entered a claim to the prize.

Queen Victoria-street Subway.—The London County Council have received an application from the City of London Electric Lighting Company for permission to place additional electric light mains, in bitumen casing and iron pipe, in the Queen Victoria-street subway, between St. Andrew's-hill and Water-lane. The Council have sanctioned the laying of these mains upon condition that the work is carried out under the supervision of the Council's chief engineer and at the cost of the company.

The Rabbidge Telephone.—A price list of the Rabbidge telephone has reached us from the India Rubber, Gutta Percha, and Telegraph Works Company, of Silvertown. This type of telephone has been designed for conversation over short lengths of line, as, for instance, in the case of communication between various offices, warehouses, etc., forming a group of buildings, or between the different rooms of a large warehouse or block of offices. The telephone can be easily manipulated, and the articulation is loud and distinct.

The Brighton Demand Indicator.—Considerable interest is being manifested in the Brighton demand indicator and its working, owing to its having materially improved the load factor at the Brighton station, and the units consumed annually per lamp installed. In this connection, Mr. Arthur Wright, the inventor, points out that the main idea involved in the Brighton system of charging was gathered from a letter of Prof. Kennedy, published at the end of 1892, in which he suggested the use of a recording ammeter, to be placed on the consumer's premises.

Stirling.—The Town Council, as mentioned in our last issue, had decided to oppose the application of the Caledonian Electric Supply Company for a provisional order to supply Stirling with electricity, and had also resolved to again apply for an order themselves. A petition to this effect was signed by the majority of the members and forwarded to the Board of Trade. The town clerk has now received a telegram from the Council's parliamentary agents in London to the effect that they have received a letter from the Board of Trade stating that they do not propose to proceed with the company's order.

Royal Meteorological Society. — An ordinary meeting of this society will be held at 25, Great George-street, Westminster, on the 18th inst. The president, Mr. Richard Inwards, F.R.A.S., will deliver an address on "Some Phenomena of the Upper Air." The meeting will be adjourned about 9 p.m. in order to afford those present an opportunity of inspecting the exhibition of instruments, drawings, and photographs relating to the representation and measurement of clouds, and of such new instruments as have been invented or first constructed since the last exhibition. This exhibition, which was opened on Tuesday, will close on Friday next.

The Lyons Exhibition.— There will be several electric tramways at the Lyons exhibition to be held this year. The first of these will be constructed by the Creusot Works, from the designs of M. Lombard-Gerien. It will be on the overhead conductor system, and it is proposed to use an alternating current of high potential in conjunction with transformers. On the second tramway, which will be constructed by the Compagnie de Fives-Lille, it is intended to employ polyphase currents. This line will only be worked experimentally, and no passengers will be carried. A tramway on the accumulator system will also be in operation, as well as one worked from overhead conductors by continuous current, the latter being designed by M. Claret. Electric lighting will be well represented at the exhibition.

The Driving of Wharf Cranes by Electricity.— Considerable interest is being manifested in the use of electricity for operating wharf cranes, and it is believed in timber trade circles that the firm who first bring out a thoroughly satisfactory electric jib crane for the use of timber merchants will have a wide field before them. It is submitted from the point of view of the latter that one of the features of advantage of electricity is that it admits of utilising the dynamo for cranework and lighting, no cranework being required after dark, and no lighting in the daytime. This fact, together with the advantage of being able to convey the power to any part of the timber yard without danger of fire, etc., offers a great inducement to timber merchants to generally adopt electricity for lighting and power purposes.

Woking Central Station.—The complete control of the Woking Electric Supply Company has been obtained by Messrs. New and Mayne, who are making alterations and improvements to the plant as will enable a considerable increase in the output of the station to be made. At present there are some 3,500 lights connected, and there is every prospect of greatly and rapidly adding to these. The chief alterations now being made are in the direction of reducing the coal consumption, running the machines synchronously, and automatically switching on and off the primaries of the single transformers for load and no load, as also in the cases where two or more transformers are running in parallel. This latter improvement is being made by means of the firm's automatic transformer switch, a notice of which appeared in our columns some time ago. There are already laid 10 miles of cable, which cover a large district, and many extensions are being carried out.

Rules for Electrical Construction and Operation.—We have received from Mr. W. J. Hammer, of 1,301 and 1,302, Havemeyer-building, New York, an advance copy of the standard rules recently adopted by the National Electric Light Association for electrical construction and operation. These rules are the outcome of the efforts of

Digitized by Google

the association to induce insurance companies to recognise the necessity for a uniform code of instructions under which intelligent workmen and inspectors can act in harmony. The rules concern the erection and working of different electric light systems, and, in addition to the former rules and those adopted recently at the Washington Convention, the pamphlet is supplemented by the report of the special committee on the rating of arc lamps and a glossary of electrical terms. It is proposed to secure the general adoption of these rules in the United States. Mr. Hammer, it may be mentioned, is the chairman of the committee of the association on the subject.

A Large Transmission Scheme.—The Clear Lake Electric Company, has been formed at Sacramento, California, for the purpose of transmitting 40,000 h.p. from a point near Rumsey, Yolo County, to San Francisco, a distance of 75 miles. Water is to be taken from Cache Creek, the overflow of Clear Lake, at a point near Rumsey, whence it will be taken through three water-mains, each 6ft. in diameter, for a distance of 10 miles, where a fall of 500ft. will be attained. This will give, as mentioned, about 40,000 h.p. One interesting feature of the scheme is the method by which it is proposed to carry the power across the bay of San Francisco. The geography of the country is such that this must be done, otherwise the distance of transmission would be increased to probably 150 miles. It is intended that the line potential shall be 25,000 or 30,000 volts, and that step-down transformers shall be placed in a sub-station located at or near the water front of Oakland, whence the current will be taken at a materially lower potential across the bay into San Francisco, a distance of eight or ten miles.

Electrical Communication with Lighthouses.—The Royal Commission on Electrical Communication with Lighthouses and Light-vessels have presented their second report, which recommends the establishment without delay of electrical communication by aerial wires between the telegraphic system of the country and a number of shore lighthouses and lighthouse stations. The Commissioners state that it is with regret that they have decided to confine their recommendations in this report to shore lighthouses; but until more has been done towards perfecting the communication of those light-vessels and lighthouses which were mentioned in the previous report as having the strongest claim to immediate attention, the Commissioners hesitate to add to the list of light-vessels and rock lighthouses with which they consider that electrical communication should be made. The report also recommends that the general lighthouse authorities should be invited to consider the general question of signalling with a view to institute a universal system of visual and sound signals at all the various light stations on the coast of Great Britain and Ireland.

Deputation on the Pacific Cable Question.—An important deputation waited upon the Marquis of Ripon (Secretary of State for the Colonies) at the Colonial Office on Thursday of last week, the Earl of Rosebery (the Prime Minister) being present. The deputation was composed of Sir Charles Tupper (High Commissioner for Canada), Sir Charles Mills (Agent-General for the Cape), Sir Saul Samuel (Agent-General for New South Wales), Sir Andrew Clarke (Acting Agent General for Victoria), Sir James Garrick (Agent General for Queensland), Sir Robert Herbert (Agent-General for Tasmania), and Sir Westby Perceval (Agent-General for New Zealand), together with Sir Thomas M'Ilwraith and the Hon. Robert Reid, special commissioners in London for Queensland and Victoria respectively. The object of the deputation was to place three requests before the Government, one being that the Imperial Government should unite with Australia and Canada in the formation of an Imperial and colonial guarantee of the interest upon the £1,800,000 needed for the construction of a Pacific cable to be confined to British territory. Sympathy with the request was manifested by Lord Rosebery and Lord Ripon, and it was pointed out that the question would be considered at the conference to be held in June at Ottawa, at which the Imperial Government will be represented.

The African Transcontinental Telegraph.—It appears, from information furnished by the British South Africa Company's office at Cape Town, that the telegraph company which Mr. Rhodes formed last year in London shipped to South Africa 400 miles of telegraphic plant, with iron poles and wire insulators of the same pattern as used for the wire connecting Cape Town with Fort Salisbury. Of this plant 200 miles was sent to Beira, and thence, *vid* the Beira Railway and by ox-wagon, transported to Salisbury for the section of the line between that place and Tete on the Zambesi, traversing the auriferous Mazoe district. The other 200 miles of plant was sent to the Chinde mouth of the Zambesi and thence carried by steamers to Tschekwawa, a place about 140 miles up the Shiré River. Of this 200 miles, 80 miles is being constructed backwards in a westerly direction to connect Tschekwawa with the Zambesi at Tete. The remaining 120 miles is to be erected northwards to Blantyre and Zomba, the British Consulate in the Shiré highlands of Lake Nyassa. Some months ago constructors were sent to Tschekwawa, and they have already constructed some 50 miles of the 80 miles connecting the Shiré with the Zambesi. Of this, 20 miles, completed and in working order, is in the Portuguese territory. The southern section of 220 miles between Salisbury and Tete is being erected under the superintendence of Mr. Gordon, a nephew of the late General Gordon. This section crosses the Zambesi to join the Shiré section at Tete, where, the river being broad, it was proposed to erect a lofty iron pole on an island in midstream.

Can Gas Shareholders Vote on Electric Lighting?—The question as to whether gas company shareholders who are members of town councils have the right of voting on electric lighting matters at meetings of these authorities has been warmly discussed recently in different parts of the country. In this connection, the opinion of Mr. George Humphreys, Q.C., sought by Alderman Powell, of Monmouth, will prove of interest: "Proceedings at meetings of town councils are regulated by s. 22 and Schedule II. of the Municipal Corporations Act, 1882 (45 and 46 Vic. c. 50). By rule 13 of Schedule II. the council may make standing orders for the regulation of their proceedings and business, but from the fact that none was referred to I assume that there is no standing order of the Monmouth Town Council applicable to the case. That being so, the matter depends on sub-section 3 of section 22 of the Act, which provides that a member of the council shall not vote or take part in the discussion of any matter before the council or a committee in which he has directly or indirectly, by himself or his partner, any pecuniary interest. In my opinion, the mere fact that Mr. Alderman Powell and Mr. Howse are directors of the Monmouth Gas and Water Company did not cause them to have within the true meaning of section 22, sub-section 3, a pecuniary interest directly or indirectly in the matter in question. I think, therefore, that the Mayor was bound to treat them in all respects in the same way as an ordinary member of the Council, and that the mere fact that they are directors of the Monmouth Gas and Water Company does not disable them from taking part in the discussion of or from voting upon the scheme for electric lighting."

The Regulation of Pressure in Electric Light Circuits.—A paper on "Some Methods of Regulating Pressure in Electric Light Circuits" was read on the 4th inst., by Mr. Wilfrid S. Boult, A.M.I.C.E., before the Liverpool Engineering Society. The author, after pointing out the necessity for very exact regulation of pressure in currents running incandescent lamps, owing to the greatly enhanced variation of light due to a small variation of pressure and the quick destruction of the incandescent filament if a large access of pressure takes place, referred to the Board of Trade limitations, and the question was then considered under the following heads: irregular speed of engine; varying terminal E.M.F. of dynamo with varying load; varying loss of E.M.F. in feeders to mains with varying load; and varying loss of E.M.F. in mains, service lines, and house wiring. Descriptions were given of the Willans-Crompton-Hartnell, the Porte-Manville, the Goolden-Lewis, the Richards, and the Jamieson governors as used with continuous current for regulating speed of engine or excitation of dynamo. Compound winding, feeder regulation, the three-wire system (with and without accumulators), in which the Manchester, Burnley, and Paris (Place Clichy) installations were instanced, with a reference to Dr. Hopkinson's station voltmeters without pressure wires, completed the consideration of continuous currents. Under the head of alternating currents, the Westinghouse, Ganz, Thomson-Houston, and Lowrie-Hall methods of regulation were described and commented upon. Numerous diagrams were exhibited illustrative of the various apparatus and methods described in the paper, which was stated to be written more for the purpose of affording to non-electrical engineers a general insight into the present state of the question than with the object of being interesting to the electrical expert.

Electric Illumination.—In his second lecture on electric illumination, delivered on Tuesday at the Royal Institution, Prof. J. A. Fleming began by briefly describing several forms of photometer, including Ritchie's and Bunsen's. He referred to the uncertain and unsatisfactory character of the unit of light supplied by the so-called "standard candle," and mentioned among suggested substitutes the amyl acetate and pentane flames of von Alteneck and Harcourt. He then passed to the consideration of glow or incandescent lamps. In all successful lamps of this type yet constructed the substance made incandescent has been carbon, it has been contained in a high vacuum, the lamp itself has consisted of a glass vessel, and the current has been led through the glass by platinum wires. The carbon filament is prepared from parchmentised paper or cellulose, and when finished is as elastic as steel. As it becomes longer when heated, provision must be made to prevent it from breaking. The horseshoe form of filament allows expansion freely, but a straight filament is mounted on a spiral spring. The vacuum in the bulb is produced by means of mercury air-pumps of various forms. Prof. Fleming also described the arrangement of lamps in series and parallel, and insisted on the necessity of a constant and uniform pressure if lamps were to have a long life. He then turned to the molecular physics of a lamp. Although a high vacuum, the space inside the bulb is by no means empty; besides a very considerable number of molecules in the air, it contains particles of carbon thrown off from the filament. These particles, which are the cause of the blackening of the glass often seen in lamps, are negatively electrified, as was shown by Edison. He placed a platinum plate in a lamp between the legs of the horseshoe filament and connected it through a galvanometer to the positive terminal. When a continuous current was passed through the lamp, the galvanometer was deflected, but if the connection was made to the negative terminal there was no deflection. The lecturer concluded with some remarks on the use of incandescent lamps.

Photometry at the Society of Arts.—The first of the series of Cantor lectures for the session of 1894 was delivered at the Society of Arts last week by Captain Abney, C.B., F.R.S., the subject being photometry. The lecturer said that the question was one which entered into our daily life and into the happiness of our homes, and he would treat it so as to give some idea of the general principles, restricting his remarks that evening to the scientific aspect. The term "photometry" had come to mean almost exclusively the science of the measurement of our household light. It was not possible, at present at least, to measure every kind of light. The measurement was made by the comparison of the illuminating values—by reflection from a screen, for instance. The most important thing to do was to fix a standard. Parliament had fixed one—viz., a candle, six to the pound. With this he disagreed entirely, as the standard could not be constant. The sperm candle was no longer what it was, and this was due to its improved quality. He showed the necessity of an unalterable standard, which should always give the same quality of light. There was one method which the lecturer said he had used with success in collaboration with General Festing for more than 10 years. This was the electric light, which was always the same. He mentioned incidentally that the methods used by him and his colleague appeared to have been rediscovered by a French *savant* within the last two years. The lecturer then proceeded to illustrate his remarks by projecting the image of the electric arc on the screen, showing that the light in the crater was very constant. Electric light was the whitest of all lights. Three different lights were compared—viz., the candle, gas, and oil—the difference of colour being shown. Light of any colour could be matched with an incandescent lamp, showing that all the lights which we use are due to incandescent carbon. This, of course, has always been suspected, and he proceeded to demonstrate it by analysing the flame of a candle. At the second lecture, delivered on Monday, the lecturer described the different methods of photometry. The lecturer said that, dismissing the standard candle test as imperfect, as he had explained in his first lecture, he would limit himself to the consideration of three only of the secondary standards—namely, the acetate of amyl lamp of Dr. von Hefner Alteneck, the pentane lamp, and the method known as the grease-spot. In the acetate of amyl system, which he greatly approved, he showed that the variation in the compounds of amyl employed made very little difference, and this had been ably investigated by Dr. Siemens. The pentane lamp, a 10-c.p. lamp, worked out by Mr. Dibdin and Mr. Sykes, was a very permanent standard and also simple and easy to work. The great point in photometry was to have a light of the same quality throughout. The method of comparison of two lights was then illustrated and explained. An interesting description and demonstration of the grease-spot method was then given, the nature and preparation of the discs (including Dibdin's improved disc) was explained, and the system of measurement with the standard light on one side and the light to be tested on the other was illustrated with the instruments themselves and by diagrams projected on the screen.

Electric Transmission of Power in Sweden.—Mr. Rob. Dahlander, of Vesterås, in an article in the *Elektrotechnische Zeitschrift* on the electric transmission of power installation at Hellsjön-Grängesberg, in Sweden, states that the late Mr. Jonas Wenström independently

Digitized by Google

discovered the principle of the rotary current, and that the owners of his Swedish and Norwegian patents (the General Swedish Electricity Company, of Vesterås) have since 1890 been busily engaged in the construction and development of rotary-current machines. The first large installation carried out by the firm has been the newly-completed power-transmission plant in the Dalecarliens mining district, between Hellsjön and Grängesberg. Water power is obtained from a small stream at Hellsjön, a fall of 150ft. being available. The water is conveyed to the power-house by means of piping 1,700ft. in length, which is partly of wood and partly of wrought iron. There are four turbines of 100 nominal horse power, and one of 20 h.p. The large turbines run at 600 revolutions, and each is connected with an alternating dynamo by means of a clutch. The small turbine drives two direct-current dynamos of 3·3 kilowatts capacity of the ordinary Wenström type, which serve to excite the alternators. The generators have 14 poles, and at 600 revolutions give a frequency of 70 periods. This frequency was chosen as, in consequence of the long distance of the transmission (over eight miles), transformation was necessary. In other installations by the same firm where transformation is not required, a low frequency is generally adopted. The four generators are all alike. Two of them produce rotary current for the transmission of power. In the third machine, which serves for lighting purposes, one of the armature coils is cut out, and both the others are connected in series so that a simple alternating current is produced. The rotary-current generators work at a pressure of 150 volts per phase, and the lighting generator has consequently an E.M.F. of 260 volts, which is, however, raised to 270 volts by increasing the excitation. The fourth generator was intended as a reserve, but it is often employed for the transmission of power. The current is led to two switchboards, one of which serves for the power transmission and the other for the lighting and the exciting circuits. There are three transformers, two of which are for power and one for light. The pressure of the current for power purposes is here raised to 5,500 volts, and that of the current for lighting to 5,000 volts. Originally the neutral point of all the transformers was directly connected to earth. This, however, caused disturbances in the neighbouring single telephone conductors. Consequently, an earth-plate was brought into use, and the connections were so made that the pressure between the neutral point and the earth would not exceed certain limits. As a further precaution, the telephone wires were partly doubled. From the generating station five conductors are carried on oil insulators on posts. Where railways or roads are crossed, the current is conveyed by means of underground cables, but overhead wires are now being substituted for these, due safety being afforded by protecting nets. The current is utilised for lighting and for power at different portions of the Grängesberg mining field, the distances from the generating station varying from 5½ miles to eight miles. At present six motors are used, with an output of from 9 h.p. to 45 h.p., and are employed in working winding engines and pumps. The motors are of a synchronous type. Each motor has a special transformer. Friction couplings are employed to connect the motors with the machinery which they drive. Eight transformers are used in connection with the lighting, with an output of from 4·5 to 10 kilowatts, each of which supplies a group of lamps. At present there are 300 incandescent lamps and 25 arc lamps employed.

Coal-Getting by Electricity.—A paper on this subject was read last week by Mr. R. S. Williamson, of the Cannock and Rugeley Colliery, at a meeting of the South Staffordshire and East Worcestershire Institute of Mining Engineers at Birmingham. The author, after explaining the various parts of the Jeffery electric holing machine, gave particulars of the results of its working. He said that about the end of November his firm made arrangements to try one of these machines, and so far it had given satisfaction. They first commenced by using a machine to hole 4ft. under by 3ft. wide cut, and had since adopted a second machine to hole 6ft. 6in. under by 3ft. 6in. wide. It was put into the bass coal seam, as the holing in this seam was very hard. Difficulty was experienced in getting workmen to work the coal at what was considered a fair and reasonable getting price; but since the introduction of the machine this difficulty had disappeared. So far the machine had been worked by men at a daily wage, other workmen being engaged to do the blowing, loading up, and putting on the cogs. They employed three men with the machine—one man to superintend and work it, another to clear the dirt away, etc., the third to assist generally. In America, he was told, two men work the machine. The average distance from the generating station to the face of work was 750 yards. When they first commenced from the rib the roof was good, and an average of over 50 cuts in eight hours could be made. Since then the weight had broken the roof, and now 35 cuts was about a fair average. In an eight-hours' working shift the length of face cut, 4ft. under, was, on December 5, 40 yards, and on December 6, 65 yards; whilst the yield was 75 tons and 122 tons respectively. The total cost on December 5 was £1. 2s., and on December 6, £1. 8s. The cost per ton for machine was 3·50d. on December 5, and 2·16d. on December 6. The cost per ton for hand labour was 1s. The author was of opinion that the wear and tear on the machine would be very much less if the working parts were made stronger. The machine was better adapted for seams having good roofs and those of a non-fiery nature. One drawback was the length required from the working face to the back timber, or cog. In conclusion, he stated that the sparking from the brushes and commutator in their present form prevented the machine from being adopted in fiery mines. Some notes were read on Tuesday by Mr. Crankshaw, before the Manchester Geological Society, on Hurd's pneumatic electric coal-cutting machine. He stated that they had three methods of driving to choose from—steam, compressed air, and electricity. Steam, however, might be set aside at once as impracticable. There was much to be said in favour of compressed air. It was safe, and helped to cool and ventilate the workings, but the loss in transmission was very great. Electricity could be transmitted by the loss of not more than 5 per cent., and now that the difficulty from sparking had been overcome, it was, he considered, the motive power of the future. Hurd's machine was a combination of the two. It had the advantages of compressed air whilst the motive power was electricity, and, taking the mechanism and motive power together, it was decidedly the best machine he had yet seen. Briefly stated, it consisted of a cutter-bar drill and an electric motor connected by suitable gearing. Mr. Crankshaw then gave some technical details with regard to the construction of the machine and its method of working, remarking that it had a strong, neat, workmanlike appearance, and gave the impression of being able to stand the rough-and-tumble of the mine, from ironstone nodules in the coal to falls of roof on the face, without much damage. Mr. Hurd, the inventor of the machine, who was present, said, judging from the results already obtained in Yorkshire with the machine, that he had no hesitation in putting the saving, as compared with hand labour—even with the compressed-air machines of the old type—at from 1s. to 3s. per ton.

PRACTICAL INSTRUMENTS FOR THE MEASUREMENT OF ELECTRICITY.

BY J. T. NIBLETT AND J. T. EWEN, B.SC.

XIX.

(Continued from page 348.)

RESISTANCE, *continued.*

Silvertown Testing Set.—This portable testing set, made by the Silvertown Company, consists of a couple of boxes—one containing a number of primary cells, and the other a galvanometer, collection of resistance coils, contact-maker, and other requisites for determining the conductor and insulation resistances of telegraph or telephone cables, electric light or power circuits, or other systems of insulated conductors.

The battery is divided into two parts—one for use in the measurement of conductor resistances, and the other for insulation. The former of these consists of four low-resistance Leclanché cells, giving an E.M.F. of about six volts, and is for use with the Wheatstone's bridge when testing the conductor resistance of a cable or other conductor for which an appreciable current is necessary. The other portion of the battery is arranged so as to give very small currents of high potential, and consists of 30 Leclanché cells of low resistance,

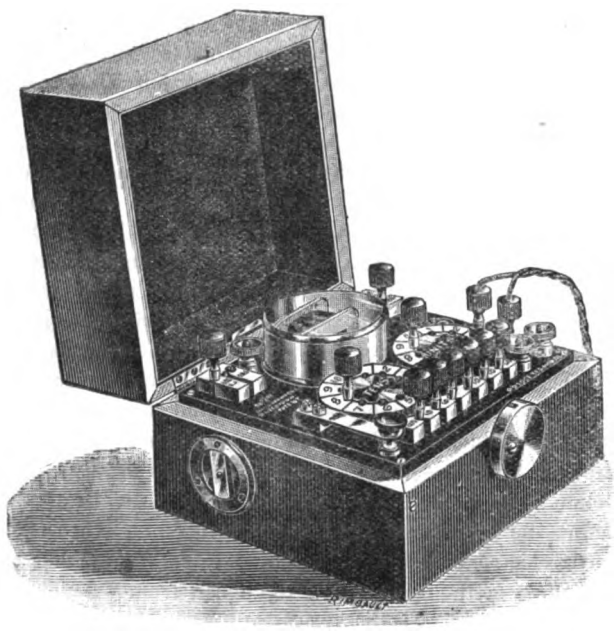

FIG. 46.—Silvertown Testing Set—General View.

capable of giving out an E.M.F. of 45 volts or more. These 30 cells are divided into three sets of 10 cells each, so that the whole, two-thirds, or one-third of the potential can be readily obtained. In the instructions issued by the Silvertown Company for the management of their testing sets, they expressly warn users not to use the high-potential battery with the bridge, or, in fact, to couple them up at all through a low resistance, as they would very quickly run down, and a considerable time would elapse before they regained their normal E.M.F.

The rest of the apparatus constituting the testing set is shown in Fig. 46, and is illustrated diagrammatically, with the under-board connections indicated, in Fig. 47. It includes a galvanometer with shunts and controlling magnet to alter the sensibility, a Wheatstone's bridge, set of resistance coils, terminals, and contact-maker. The connections between the two boxes are made by means of insulated flexible wires terminating in plugs, as shown in Fig. 46, and those between the apparatus and the conductor whose resistance or insulation is being measured, are made by flexible wires and binding screws in the usual way.

The galvanometer consists of a light magnetic needle swinging through an arc of about 90deg. in a coil of high resistance. The needle is so suspended that when the lid of the box is closed, it is lifted off its agate centre by means of the projecting lever shown in Fig. 47. This is of great importance in a portable instrument, as the fine suspension would be almost certain to get damaged were the needle point allowed to rest in the jewel when the apparatus is being carried about. The needle can be readily taken out and examined on withdrawing from the interior of the coil the slide on which it is pivoted, after removing the glass cover. The deflections of the needle are read off from a light aluminium pointer attached at right angles to the needle and projecting through the end of the coil to a calibrated scale, as shown in Figs. 46 to 49. The north end of the magnetic needle points towards the left side of the box when in its normal position, so that the aluminium pointer should point to the magnetic west when indicating zero on the scale.

The controlling magnet, as shown in Fig. 46, is pivoted on the side of the box in such a position that when the needle is hanging normally in the coil, its north pole points directly towards a vertical line drawn through the centre of the magnet. With the north pole of the controlling magnet uppermost, its effect upon the needle is opposed to that of the earth, so that the magnetic field in which the needle swings is weakened, and the galvanometer rendered more sensitive. With the south pole uppermost the earth's magnetic field is strengthened, the needle oscillates more rapidly, and the galvanometer is rendered about 40 per cent. less sensitive than before. The magnet is generally placed with the north pole uppermost so as to be as sensitive as possible when measuring high resistances such as insulation, and with the south pole uppermost when measuring conductor resistances. The galvanometer pointer can be brought accurately

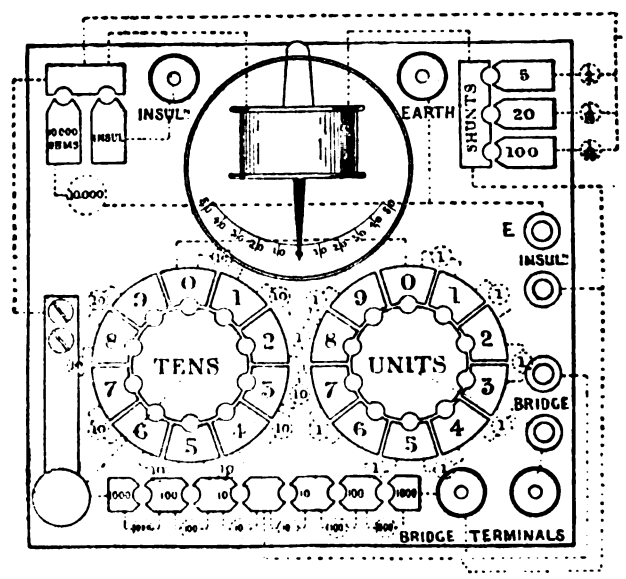

FIG. 47.—Silvertown Testing Set—Plan showing Connections.

to zero by slightly deflecting the controlling magnet to right or to left. In other examples of these testing sets the controlling magnet is a round bar about 2½ inches long and 3-16ths inch diameter placed above board at the left of the galvanometer, and so mounted that it can be moved out or in and turned round in a horizontal plane.

The galvanometer shunts, as shown in Figs. 47 and 49, are capable of reducing the current flowing through the galvanometer to $\frac{1}{1}$, $\frac{1}{10}$, or $\frac{1}{100}$ of the whole current generated by the battery; and in other examples only two shunts are provided, having values of $\frac{1}{10}$ and $\frac{1}{100}$.

The positions of the different resistance coils and all the under-board connections, are illustrated in Fig. 47. The coils and connections specially required when measuring conductor resistances are shown separately with the others omitted in Fig. 48, and similarly those for insulation resistance in Fig. 49. Before making a test the apparatus box should be placed on a level, or approximately level, surface with the galvanometer pointer towards the magnetic west and the controlling magnet vertical. The pointer can then be brought exactly to zero by slightly turning the magnet.

Measuring Conductor Resistance.—The parts of the apparatus used when measuring conductor resistance, as shown in Fig. 48, are the galvanometer, adjustable resistance, ratios, contact-maker, and four terminals. The shunt coils are omitted because they are not essential to this test, although

Digitized by Google

before a balance is arrived at and the galvanometer deflections are inconveniently large, the galvanometer is sometimes shunted temporarily. The adjustable resistance consists of the two dials marked TENS and UNITS, the former containing nine 10-ohm coils, and the latter nine 1-ohm coils; and the ratios consist of pairs of 10-ohm, 100-ohm, and 1,000-ohm coils. The four low-resistance cells in the battery-box are attached by flexible leads with plug ends to the two plugholes marked BRIDGE, Fig. 48; and the ends of the conductor whose resistance is to be measured are connected to the two terminals marked BRIDGE TERMINALS. The plugs at the ends of the battery leads are shown in position in Fig. 46. The conductor resistance is then measured in the usual way by the Wheatstone's bridge method, as described under this head in a former article.

Suppose, for example, that the 100-ohm coil on the left side and the 10-ohm coil on the right side of the ratios are left unplugged, and that with 2 in the TENS coil and 6 in the UNITS the galvanometer gives a deflection of half a division to the right, while with 2 in the TENS and 7 in the UNITS the pointer indicates two divisions to the left.

R_1 therefore lies between 26 and 27, and is nearer to 26 in the ratio of **2** to $\frac{1}{2}$, so that it is = 26·2 ohms.

R_2 = 10 ohms and R_3 = 100 ohms.

$$\therefore R = R_1 \times \frac{R_3}{R_2};$$

$$= 26{\cdot}2 \times \frac{100}{10};$$

$$= 2{\cdot}62 \text{ ohms.}$$

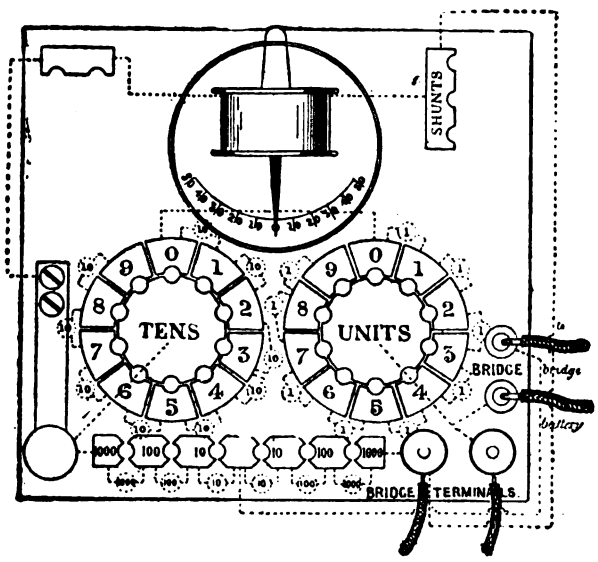

FIG. 48.—Silvertown Testing Set—Conductor Resistance Connections.

When measuring so small resistances as these it is highly essential to ensure good contacts at all the junctions, as the slightest extraneous resistance introduced into the circuit, whether from dirty or corroded terminals or imperfect clamping, is liable to entirely vitiate the results obtained. The Silvertown Company recommend the soldering to the ends of conductors, brass or copper plates slotted to pass under the loose head of the clamp terminal, so as to obtain an efficient contact. Again, although the internal resistance of the Leclanché cell used is low, they develop but a small E.M.F., and if allowed to remain long in circuit quickly polarise, so that they should be allowed to remain actually in circuit only so long as the galvanometer reading is being taken.

Measuring Insulation Resistance.—For this test all that is required is the galvanometer and shunts, the 10,000-ohm resistance coil, the block alongside it marked INSUL., and the four insulation terminals. The contact-maker at the left bottom corner is used to short-circuit the galvanometer. The conductor whose insulation is to be measured is connected to the terminal marked INSULN. at the top left corner, the other terminal, marked EARTH, being connected to earth or to the sheathing of the conductor. The terminals of the high-potential battery, consisting of 30 Leclanché cells, are attached by means of the flexible leads to the two plugholes marked INSULN. at the right of the apparatus box. As already described, this method consists in comparing the deflections of the galvanometer with a high resistance—10,000 ohms in this case—in circuit, and with the insulation of the conductor in circuit, the galvanometer being shunted in either or both cases, if required, to bring the deflection within measurable limits. The insulation resistance, R, is then found from these observations by the formula already given:

$$R = R_1 \times \frac{d_1 s_1}{d s},$$

where R_1 = 10,000 ohms, d the deflection, and $\frac{1}{s}$ the shunt used with R in circuit, and d_1 the deflection and $\frac{1}{s_1}$ the shunt used with R_1 in circuit. R_1 is put into circuit by plugging the block at the top left corner, marked 10,000 OHMS, and R is put into circuit by plugging the block marked INSUL. When neither of these is plugged the circuit is entirely open.

It is usually found in practice that it is necessary to employ the highest shunt power when the 10,000-ohm coil is in circuit if the whole of the 30-cell battery is used. With the insulation of the conductor in circuit, a lower shunt power is usually found ample, or no shunt at all when the insulation resistance is very high. As an example, suppose that with the 10,000-

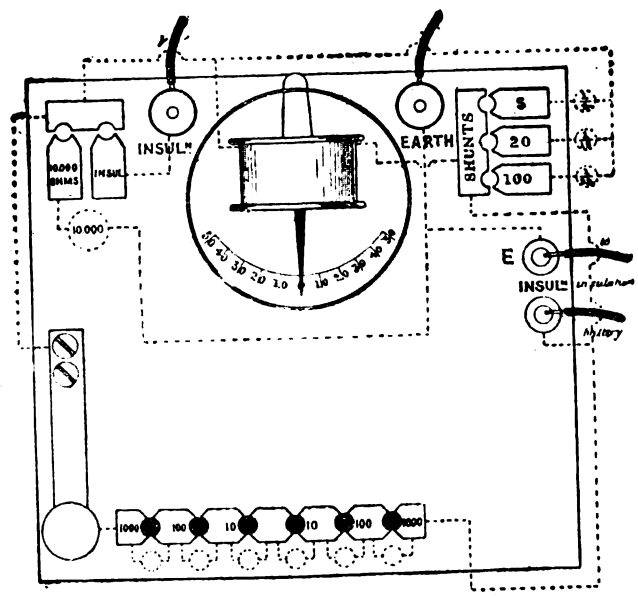

FIG. 49.—Silvertown Testing Set—Insulation Resistance Connections.

ohm coil in circuit and the galvanometer shunted to $\frac{1}{100}$, the deflection obtained is 27; and with the insulation in circuit, and the galvanometer shunted to $\frac{1}{20}$, a deflection of 15 is obtained. The insulation resistance, R, will be found as follows:

$$R = 10{,}000 \times \frac{27 \times 100}{15 \times 20};$$

$$= 90{,}000 \text{ ohms.}$$

Had the insulation been so perfect that a deflection of only 12 was obtained with the galvanometer unshunted, its resistance, R, would have been instead:

$$= 10{,}000 \times \frac{27 \times 100}{12 \times 1};$$

$$= 2{,}250{,}000 \text{ ohms};$$

or, $= 2\frac{1}{4}$ megohms.

(To be continued.)

SOME NEW POINTS IN DYNAMO DESIGN.*

BY H. A. MAVOR, M.I.E.E.

I propose to bring before you some considerations which have been suggested by the development of a type of dynamo which my firm is now manufacturing. This machine was invented by Mr. W. B. Sayers. Before passing to these considerations it may be well, in order that the novel arrangement may be fully understood, to recall some important points which have to be considered in the design of continuous-current dynamo machines generally. For our present purpose we may practically confine our attention to the consideration of the two essential elements of the dynamo—viz., the magnetic and the electric circuits. (The useful part of the electric circuit being defined as that part which moves across at right angles to the magnetic field. The useful magnetic circuit consists of the iron field magnets, air-space, and iron armature core.) We need not for our present purpose concern ourselves in detail with the properties of the iron in the magnetic circuit further than to mention that experience seems to prove that pure cast steel is the best material for the field magnets, and soft annealed charcoal iron is the best for the armature core. The practice in this country is to build up the armature core of alternate sheets of charcoal iron and paper (the object of the interposition of the paper being to prevent the production of electric currents in the iron moving at right angles to the magnetic field). It is important that iron of the highest attainable magnetic permeability should be used, so that as little energy as possible may be expended in producing the magnetic field.

The E.M.F. of a dynamo depends upon the number of magnetic lines of force in the part of the magnetic circuit through which the useful portion of the electric circuit moves, and upon the rate of the motion. The two main objects in dynamo design are (1) to so direct the magnetising forces that the effect produced is confined as much as possible to the space through which the electric circuit is moved; (2) to so arrange the electric circuit that as much as possible of that circuit shall come under the description of useful electric circuit—that is to say, as much as possible of the part of the electric circuit included in the armature should move across the magnetic field at right angles. To attain the first of these ends, it is necessary to direct our attention to the form of the magnetic circuit, and as the electric circuit has to move across the magnetic circuit a space must be provided for its passage: this space is called the air-space.

For economy in cost of construction and uniformity of result, it is customary to use magnets in which the magnetic induction is obtained from electric currents generated by the machine. The form of the magnetic circuit has thus to be modified to admit the necessary winding of the electric conductor. Since the magnetic induction produced by the current in the winding depends upon the permeability and length of the magnetic circuit as a whole, it is evident that, seeing iron is more permeable than air, the air-space should occupy as little as possible of the length of the circuit; and that the iron portion of the circuit should be just long enough to accommodate the necessary winding. It is evident that while the iron and the air-space form the essential portions of the magnetic circuit, the circuit is not by any means confined to this region. That portion of the magnetic lines of force which returns from pole to pole outside the useful field of the circuit is treated as "leakage." The amount of this leakage with any given induction depends upon the form of the magnets and the length of the air-space. It would be possible to so design a dynamo that the greater part of the magnetising force would be lost in this way. The ratio of total field to useful field, in dynamos of the ordinary design, varies from 1·2 to as much as 2. The great importance of keeping the air-space as short as possible will be at once evident from this consideration. The determination of the length of air-space is, however, also governed by other considerations, which we shall discuss later.

Up to this point we have been looking at the dynamo as a simple magnetic circuit in which the induction is produced by an electric current passed round the iron core.

* Paper read on March 23 before the Physical Society of Glasgow University.

We now come to consider the effect upon the magnetic circuit of the currents in the electric circuit. The distribution of the electric currents in the armature and their effects upon the induction in the magnetic circuit depend upon the position of the brushes. For the purpose of considering the reaction of the armature currents upon the magnetic circuit, the armature conductors are divided into two groups: the active and the idle conductors—those in the air-space which are cutting through the magnetic field and those in the pole gap which, for the time being, are not concerned in the generating of E.M.F., but simply connect the two active groups to the brushes. Let us consider the effect first of those in the pole gap. The reaction on the magnetic circuit of the currents will be readily understood from the diagram.

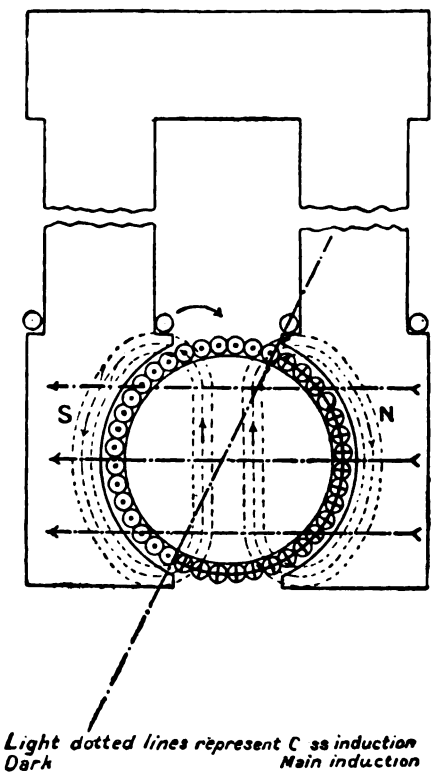

FIG. 1.—Conductors in Pole Gap.

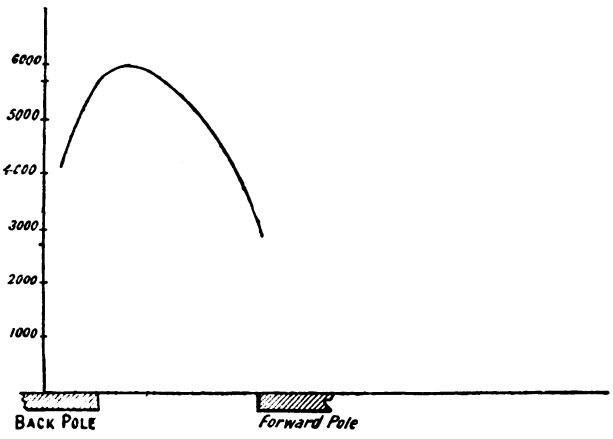
In a dynamo the brushes would be placed somewhere near the forward pole tips. All the currents to the left of the brushes react against the induction through the armature, and the magnetising force has to be increased as the current increases in the armature to counteract this effect. This is done by what is called compound winding, the current being taken round the magnetic circuit in the opposite sense to the direction of the reacting armature current. The number of ampere-turns required to compensate for the back induction must be greater than the number of ampere-turns on the armature, because while the nearly whole magnetising force of the armature-turns is effective against the induction, the magnetising force of the compensating turns is subject to leakage to the same degree as that of the principal winding. If the machine be run upon open circuit, there is no armature reaction.

It will be seen from this diagram (Fig. 2) that the further back in the direction of rotation is the position of the brushes, the less is the back induction produced by the armature current. This leads to the consideration of the elements which determine the position of the brushes, or, as this is technically described, the diameter of commutation. Having ascertained what is the most advantageous position for the brushes, having regard only to the back induction effect of the armature currents, let us see whether the brushes can be placed in this position. We shall assume that the armature is rotating in a clockwise direction and that the S. pole is to the left or rearward position. The currents in the electric circuit which is in the air-space under the S. pole will be flowing towards the observer; the currents in the air-space under the N. pole will be flowing from the observer—the E.M.F. generated by cutting the lines of force in the magnetic field being in the direction stated. But, as

Digitized by Google

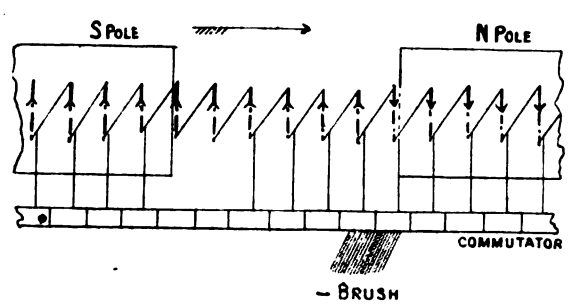
already stated, the magnetic field is not confined to the air-space; there is a flow of lines from the pole tips to the armature core extending forward into the pole gap, so that the conductors in the pole gap which are carrying the currents from active parts of the armature to the brush are some of them the seat of an E.M.F. opposing the flow of these currents. Further, as each armature coil passes under the brush, it will be seen that the current



Abscissæ = Brush Positions
Ordinates = Field Induction in C.G.S. lines per Centimetre

FIG. 2.—Diagram of Potential with Variation in Back Induction by Shifting Brushes with Full Armature Current.

in it has to be stopped and reversed in direction; but if it is still cutting lines of force so that the E.M.F. tends to keep the current flowing in the same direction, the current will be stopped and reversed only after the coil has passed from under the brush connection. Meanwhile it is short-circuited upon itself by the brush connecting its ends together and has a current set up in it, the magnitude of which depends only on the E.M.F. generated in it and on its own resistance. This current would not only waste energy by heating the coil, but by the breaking of the short-circuit would rapidly burn and destroy the brushes and commutator. It is therefore necessary to find some position of the brushes where this will not take place. Experience has shown that the necessary stoppage and reversal of the current must be accomplished by the aid of the magnetic field under the fringe of the forward pole (Fig. 3). Here it will be seen that when the coil passes



Thick dotted lines are the active Conductors of a Gramme Ring Seen through the Core

FIG. 3.—Diagram of Action of Commutation.

under the brush it is beginning to cut lines of force which set up an E.M.F. in it which tends to stop the current which has been flowing in it up to this point and to start a current in the opposite direction. In its passage across the upper pole gap, the coil has passed out of the influence of the S. pole, and the difference of potential across its ends when it begins to cut into the field of the N. pole is only that due to its resistance and the current for which it serves as a conductor; but this difference of potential across its ends and its self-induction will vary with the current which it is carrying, and therefore the best position for commutation will vary with the current which is flowing in the armature. It is for this reason that the brushes have to be moved forward as the load on the machine is increased. There is therefore in all ordinary types of continuous-current dynamos a necessary amount of back induction. It must be compensated for by an addition to the magnetising force of the magnetic circuit. This back induction, it may be repeated, is the effect of those coils in the armature which lie in the region outside the air-space. The coils which are not in this space cancel each other out as regards back induction.

Let us now pass to the consideration of the effect, upon the magnetic circuit, of that part of the electric circuit which lies within the air-space, and which is the seat of E.M.F. Returning to the diagram of direction of currents in armature we may consider first the magnetic circuit in which the cross magnetising currents lie, by itself, and then in its relation to, and reaction upon, the useful magnetic circuit of the dynamo. We find a band of conductors carrying current round the armature which act, as does the winding of any electromagnet, so as to produce a magnetisation which depends, as before, on the length and permeability of the various parts of the magnetic circuit of which the armature core forms a part, and upon the ampere-turns in the winding. (Here, again, the coils which lie outside of the air-space cancel each other out as regards cross-magnetisation.) In the diagram the direction of the flow of magnetic lines of force is represented as upwards through the armature core, and downwards across the pole-pieces of the field magnets. Taking this, now, in conjunction with flow of magnetic lines of force in the main magnetic circuit, we find that the magnetisation produced by the cross flow is such as to increase the induction in the two rear or trailing tips of the field-magnet poles, and to decrease it in the other two. Further, the cross-magnetisation of the armature and poles of the machine so effected, reduces their permeability, and this necessitates a further addition to the magnetising force in the main magnetic circuit (see S. P. Thompson, p. 93 and references).

The second of those effects is very important, as it not only affects the amount of winding required for the field magnets, but also affects the regulation or maintenance of a constant E.M.F. by the machine. The effect of cross-induction has been diminished by cross-lamination of the field magnets, although this is not often resorted to, and the regulation can be rectified by additional compound winding. The most important, however, is the effect upon the commutation of the armature currents. It will be seen that the corners of the poles which are weakened by the cross-induction are those under which it has been found best to perform the action of commutation, and it is necessary to provide that the cross-magnetisation does not so weaken this part of the field that commutation becomes impossible. This consideration fixes a limit to the possible shortening of the air-space, and to the possible current in the armature with sparkless collection at the brushes. We have, then, found certain limitations in the design of continuous-current dynamos which may be recapitulated. (1) The necessary existence of a varying amount of back induction. (2) A limitation to the reduction in length of the air-space by the necessity for keeping down the cross-induction so as to maintain the strength of the forward pole tip.

The first of these means that additional winding, and, therefore, additional length, is required in the field magnets over and above what is required to produce the induction through the armature were this back induction absent. The second means that still more additional winding is required to produce the induction across a longer air-space than is required for mechanical clearance and other requirements, of which we postpone consideration for the present.

We may now proceed to describe the modification devised by Mr. Sayers and its bearing upon these points. The device (Fig. 4) consists in the introduction, between the main winding of the armature and the commutator, of a part of a turn, a turn, or turns of wire called the "commutator coil." Two commutator coils are here shown under the brush: the armature coil which lies between them and is short-circuited by them and the brush, has just passed out of the fringe of the S. pole. The commutator coil B is in a strong part of the field; commutator coil A is passing into a weaker field. The resultant E.M.F. in the circuit which is shown with thickened lines, is thus downward in the commutator coil A, upward in the coil B, and downward in the section × of the armature between them. This E.M.F. is applied to stop the upward current in the armature section ×, so that when the position

Digitized by Google

shown in the next diagram (Fig. 5) is reached, the armature coil is having a reverse current started in it before it passes over to the other side of the field. The resultant downward E.M.F. in the commutator coil A has died down to zero, and the difference of potential between the commutator plate under the brush and the point where coil A joins the armature is only that due to the resistance of the commutator

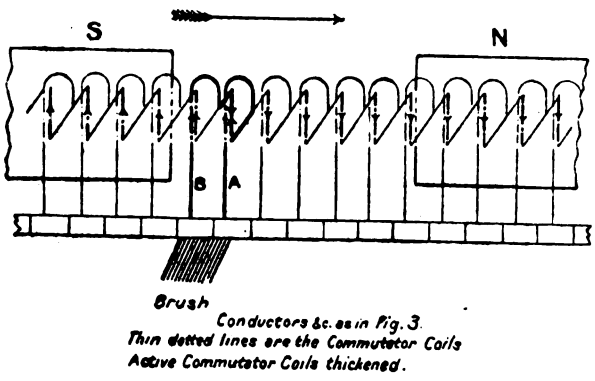


FIG. 4.—Diagram of Commutator Coils.

coil and the portion of the main current which it is carrying when its plate leaves the brush. This proportion will be small because there is an E.M.F. generated in B and C (which are still cutting lines of force), which E.M.F. assists the main current. The commutator coil must be so placed that the armature coil has passed completely out of the field before commutation commences.

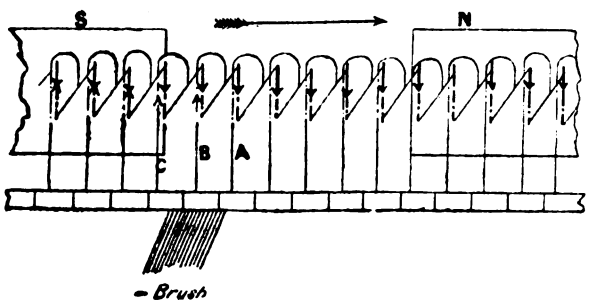

FIG. 5.

It will be seen that in an armature wound as shown in those diagrams, and with the commutator coils connected as shown, the effect of the commutator coils can only be obtained when the armature is running in the direction indicated by the arrow. Sparkless collection may be obtained when the machine is running in the other direction, but the brush must have a forward lead, and there is no advantage gained. The arrangement shown on the

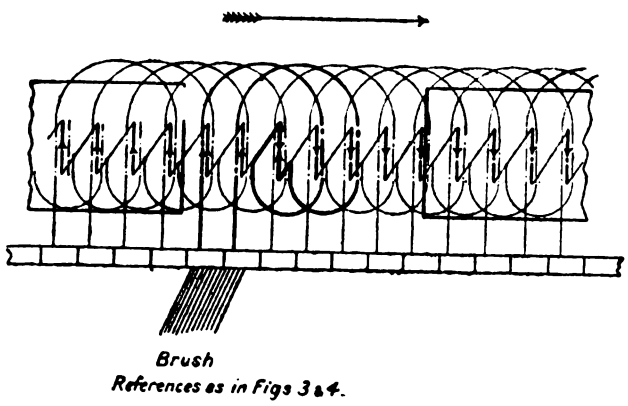

FIG. 6.

next diagram (Fig. 6) is therefore adopted. It will be seen that the connection of the coil is exactly the same, but that it has two sides—an active and an idle side; the side in operation being that which is under the pole tip when the coil is connected to the brush. Let us now examine the effect of this arrangement.

Referring again to the diagram of currents round the armature, in conjunction with the diagram of commutator coils, it will be seen that the brush is now in a backward position in relation to the direction of rotation, and that the wires between the pole gaps are not now all opposing the induction of the field magnets. In the diagram with the single commutator coils, it will be seen that of the conductors in the pole gaps. Those to the right of the brush are now assisting the induction, while those to the left of the brush are opposing the induction. The commutator coils carrying the armature current to the commutator are also opposing the induction. As the group of two or three commutator coils carries the whole armature current, this group accounts for two conductors in the main winding which carry only half the armature current. There is thus left a balance of magnetising turns. The resultant armature reaction is therefore now assisting the field induction, and machines can be and have been made on this principle without any winding on the field magnets, the armature itself supplying the whole of the necessary field. The saving in magnet winding of course results in a saving in the length of the iron magnets and a reduction in the size and weight of the machine. Further, the abolition of back induction renders unnecessary the compounding or compensating magnetising coils which are required to counteract its effects.

Coming now to the question of cross-induction, it will be seen that the cross-induction remains practically as before, but the effect of it is very different. Instead of weakening the portion of the field in which the currents are being reversed, it strengthens it, and thus the reversing effect increases with a rise of the current and consequent increase of self-induction in the armature sections—exactly what is required to produce a sparkless collection of the currents without shifting the brushes for changing loads. There still remains, however, the effect of the cross-induction upon the magnetisation. This effect is the crowding of lines in the tips of the trailing poles. The increase in the induction at this point results in a decreased permeability, and means must therefore be adopted to minimise this effect.

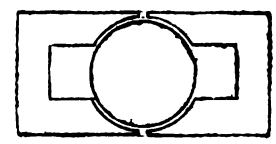

FIG. 7.

The form of magnet shown in Fig. 7 is adopted for this, among other reasons. (An account and comparison of various forms of magnets will be found in Kapp's "Dynamo Machines, Alternators, and Transformers.")

It has been shown that one of the advantages gained in this type of machine is a reduction in the length of the air-space. (The length of air-space in these machines varies from 1mm. in the smallest sizes to 4mm. in machines of 30 units), but the effect of cross induction still limits the shortening of the air-space by increasing the total flux in the poles, and thus reducing the permeability of the iron to the useful magnetising force. The calculation of this effect is, however, a simple one. The shortening of the air-space introduces other difficulties, which have to be met by a careful study of the conditions and adaptation of the design. The first of these is the heating of the pole-pieces by eddy currents set up by rapid changes in the induction caused by the alternate passage of the teeth and slots of the armature. This effect is also accompanied by a noise produced by the same means. The narrowing of the top portions of the slots or the complete closing of them, making what is known as a tunnelled core, gets over this difficulty, but increases the self-induction of the armature sections and renders necessary an increase in the reversing force.

This question of self-induction is frequently a stumbling block to students, but it need not be so. The E.M.F. which has to be set up in each armature section to stop the current which is flowing in it when it comes under the brush, is calculated precisely in the same way as the E.M.F. of the armature itself. The current in the coil is considered exactly as any magnetising current is considered, the reluctance of the iron and air of the circuit embraced by the coil and the induction in this magnetic circuit are calculated in the usual way, and the E.M.F. required to stop the current and restart it in the opposite direction, in the time during which the coil is passing

Digitized by Google

from one side of the armature to the other, is the E.M.F. generated by the introduction into and removal from the coil of the lines of force in the field surrounding the armature current (see Fig. 8).

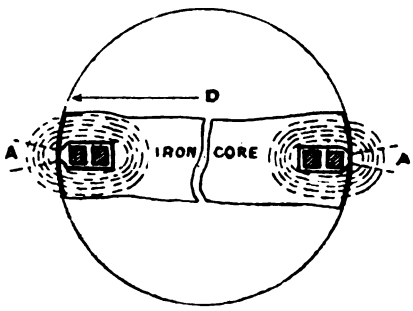

FIG. 8.—Part of Cross-section of Armature, showing magnetic field ("self-induction") round one armature coil of two turns, showing air-gaps, A A, in magnetic circuit.

The device described provides a means for producing the E.M.F. required for the reversal even where a tunnel winding is adopted, but it is better to leave an air-gap in the top of the tunnel than to increase the number of turns in the commutator coils. A tunnel so formed has the further advantage that magnetic leakage round the surface of the armature is reduced to a minimum.

A THREE-WIRE SYSTEM OF DISTRIBUTION WITH ONE DYNAMO.*

A French electrical company has recently made several interesting applications of a new system of distribution on the three-wire system by the use of only one dynamo. It is well known that the three-wire system and all methods generally of distributing current by multiple wires afford a notable saving in copper in the conductors as compared with the ordinary two-wire system. The three-wire system is usually carried out by connecting two dynamos in series, and thereby establishing a neutral point at the junction of the positive pole of one of the generators with the negative pole of the other. This neutral point serves as the place of connection with the compensating wire placed between the two outer conductors arranged one on the positive pole of one of the two generating sources connected in series, whilst the other conductor is connected with the negative pole of the system. The difference of potential between the two outer conductors, after making allowance for losses, is evidently the difference of potential at the terminals of the two generators arranged in series—that is to say, when the two generators are identical—twice that which would be produced by a single generator. The compensating wire, therefore, has in relation to the two outer wires a difference of potential equal to the half of that furnished by the entire system, so that by connecting each apparatus receiving current, on the one hand, to the compensating wire, and, on the other hand, to one of the outer conductors—care being taken to arrange matters so that as much as possible the current traversing the apparatus taking current on one side of the compensating wire is equal to the current traversing the apparatus arranged on the other side of this wire—each apparatus receiving current will only work at a pressure half less than that furnished by the source of electricity, and will, nevertheless, preserve its entire independence from the working point of view.

If the consumption of the apparatus in operation is equal on the two sides of the compensating wire, the current passes directly through the apparatus receiving energy from one outer wire into the other, and the middle wire has no current. On the other hand, if the number of apparatus is greater on one side of the compensating wire than on the other, and if the consumption is unequally distributed, the excess of current traversing the outer conductor which has the greatest charge returns to the generating source by the middle wire. This means that the quantity of current represented by the outer conductor having the lowest charge behaves exactly as in the first case—that is to say, it passes from one outer conductor into the other in traversing the receiving apparatus, and that the excess of current from the other conductor passes only into the compensating wire. The disadvantage of this system in principle is that two generators are required.

The system designed by the Compagnie de Fives-Lille allows of the feeding of a three-wire distributing network from a single dynamo, and without the production of sparking at the connection with the neutral wire. The arrangement of this system will be seen from Fig. 1, where the armature of a direct-current dynamo is revolving between two inducting poles, *n* and *s*. To simplify the comprehension of the illustration, the commutator is not shown, and the brushes, B_1 and B_2, have been placed directly on the winding, which in principle comes to the same thing. These two brushes are connected to the main cables, L_1 and L_2, which here form the two outer conductors of the three-wire system. We have seen that to establish a three-wire system a neutral point must be created in the generating system, and to which the compensating wire is connected. It is in the formation of this neutral point that the originality of the system under consideration lies.

Instead of joining two dynamos in series to obtain this result, we connect to two points diametrically opposed, *a* and *b*, of the armature of a dynamo, the two extremities of a coil, D, having great self-induction and a feeble ohmic resistance. During the rotation of the armature

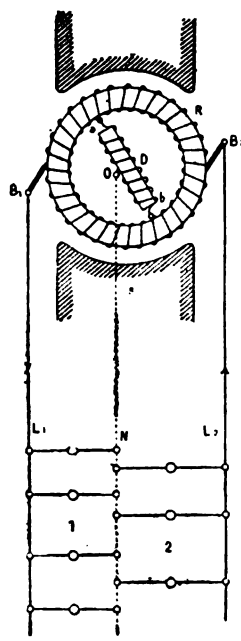

FIG. 1.

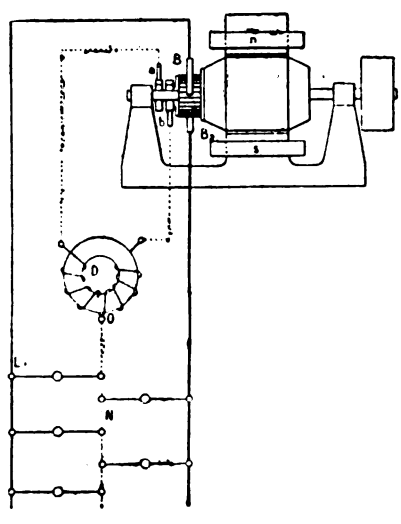

FIG. 2.

there will be produced between the points, *a* and *b*, an alternating E.M.F.; but as the coefficient of self-induction of the system has a great value, the alternating current created in the circuit will be weak. It is possible to reduce the intensity of this current as much as desired by increasing the coefficient of self-induction, L, of the coil, D, which can easily be done by arranging it on a core closed in iron. The point, O, in the centre of the coil has the mean of the potentials of the other parts of the winding, and not only is the difference of potential *a* O equal to *b* O, but at the same time the difference of potential between the points B_1 and O is equal to that existing between B_2 and O.

If we now place the compensating wire, N, by which the groups (1 and 2) of lamps are connected in series, into communication with the neutral point, O, and if the "bridges" 1 and 2 contain in operation the same number of lamps or apparatus, the neutral wire will remain without current. But if the "bridge" No. 1 is loaded more than No. 2, the excess of current of the first over the second will return to the dynamo by the compensating wire, and, reaching the point O, this current will be divided. As it is continuous, it will have no difficulty in traversing the coil, D, to penetrate the armature. It will be seen that by the aid of this device we are placed in exactly the same conditions as in the case of the use of two generators arranged in series. The

* Abstracted from *L'Electricien*.

Digitized by Google

independence of the two consuming groups is complete, and if one or the other of these groups consumes more current than the other, the pressures remain the same, since the excess of current returns to the armature almost without any loss by the neutral wire, N, and by the coil, D.

As it is not always practicably possible to revolve the coil, D, with the armature of the dynamo, we can, without inconvenience, connect respectively two diametrically-opposed segments of the commutator, as shown in Fig. 2, to two rings arranged on the shaft, and upon which press two brushes, *a* and *b*, placed in communication with the two extremities of D, having great self-induction. This coil, which in this case is fixed, is arranged in a box at the side of the dynamo, and always has, as in the preceding case, its neutral point, O, connected to the compensating wire, N.

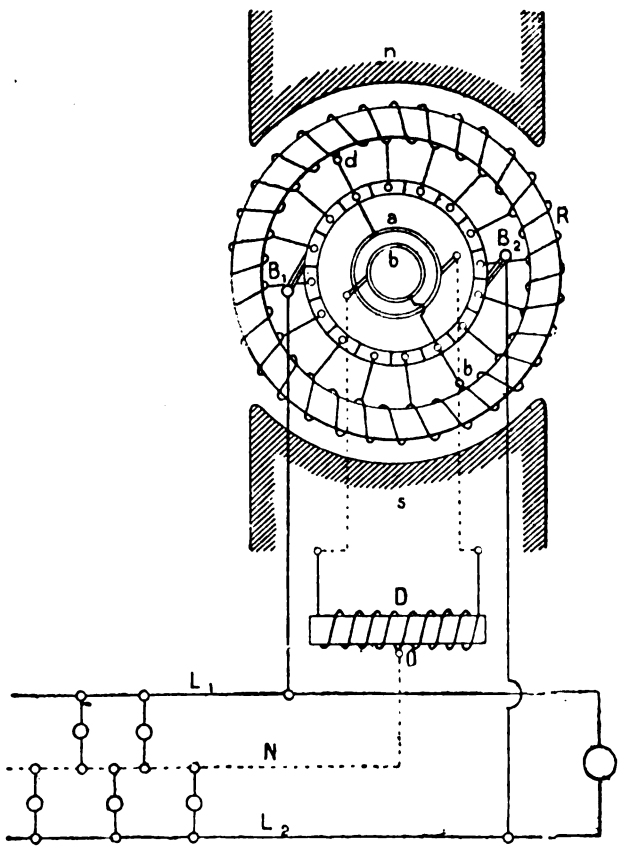

FIG. 3.

Is is very easy to employ this method for the purpose of regulating the pressure, especially in the case where the central station, as illustrated in Fig. 3, is distant, and supplies current at a pressure equal to the total tension of the two groups of lamps. In this case it is only necessary to insert near the places of utilisation one or several of these dynamos provided with self-induction bobbins. The brushes, B_1 and B_2, are put into communication with the main conductors, L_1 and L_2, in such a manner that the armature, R, commences to revolve and works as a motor; the neutral wire has not to be connected to the central station situated some distance away, and it then only serves for the compensation of the two circuits in use. This system can be applied both to dynamos and to motors, since the equalisers can work as well both as dynamos and as motors. This system can be applied to multipolar machines. This method allows of the distribution of current from 110-volt lamps in a radius of up to about 900 yards by the use of a single dynamo. This arrangement has been practically put into operation in six different instances with dynamos of 60 h.p., giving, it is said, great satisfaction.

Marseilles.—Experiments have been made in connection with a new conduit system for electric tramways, the invention of M. Chabeault. The French paper from which we abstract this item does not give any details of the system.

INSTITUTION OF ELECTRICAL ENGINEERS, Apr. 12.

Mr. R. E. B. CROMPTON in the chair.

At last night's meeting of the Institution the following candidates were balloted for:

Members.—Henry Robert John Burstall, 76, King's-road, London, N.; Alexander William Stewart, Crescent, Dalmuir, Dumbartonshire.

Associates.—Howard Tindall Adlard, 7, Northampton-park, N.; Malcolm H. Butcher, 24, Finsbury Park-road, London, N.; Charles Langstone, 8, Coleshill-street, Birmingham; J. H. Lee, Central Electric Lighting Station, Back of the Walls, Southampton; Andreas Peter Lundberg, 18, Regina-road, Tollington Park, N.; Gustaf Charles Lundberg, 18, Regina-road, Tollington Park, N.; David Mair, inspector of telegraphs, Bloemfontein Station, South Africa; George J. T. Parfitt, The Avenue, Keynsham, Bristol; Frederick William Sedgwick, Jesmond House, Epsom; Thomas Wright, 136, Bothwell-street, Glasgow, N.B.

Students.—T. D. Clothier, 13, Edwardes-square, Kensington; Dennis H. Felce, Kenmure Lodge, Elgin-avenue, W.; Herbert Grimwood, Faraday House, Charing Cross-road, W.C.; Frank Tracy Hamilton, City and Guilds Technical College, Finsbury, E.C.; Simon L. F. McLauchlan, 97, Hagley-road, Birmingham; Alec William Quennel, 44, Lower Kennington-lane, S.E.; Bernard J. Shillito, 25, Waldeck-road, Carrington, Nottingham; Frederick S. Spiers, 20, Christopher-street, Finsbury, E.C.; Frank Charles Thomas, City and Guilds Technical College, Finsbury, E.C.: James Toulmin, Linden House, Clarence-street, Loughborough; James Edward Salusbury Trelawny, 13, Lancaster-gate, W.

Prof. Ayrton read the addition printed in our last issue on "A Universal Shunt Box for Galvanometers," and also referred to certain objections which had been made, but he omitted to say where or by whom. Touching upon the question of the cost of the shunt boxes he instanced the following:

(1)	.....	10	.....	900	..... 9,000 ohms.
(2)	.....	100	.....	900	..... 9,000 ohms.
(3)	.....	1,000	.....	9,000	..... 90,000 ohms.

The estimate was the same for the third as for 1,000 ohms, and the second box was even cheaper. He stated that if the current was so small as to be hardly detectable it would be better to remove the shunt.

A brief discussion then took place on the paper on "The Best Resistance for the Receiving Instrument on a leaky Telegraph Line," written by Prof. Ayrton and Mr. C. S. Whitehead, and reported in our last issue.

Mr. W. P. Granville pointed out that in submarine cables the dielectric resistance increased greatly when the galvanometer was first applied.

Prof. Hughes said that the title of the paper was not quite accurate, for the "best resistance" would be none at all. The tests of electro-magnets should be made under the conditions in which they were used. He had made experiments, and found that the self-induction of the magnets induced an apparent resistance. The resistance of all electromagnets was too high, and his principle was to reduce resistance as far as possible. Makers had to design electromagnets for the average conditions of the line. All rapid instruments suffered from atmospheric conditions in hot climates such as Spain and Turkey.

The Author, in reply, regretted the fact that the telegraph people had not come forward to discuss the paper, as he had hoped to have drawn opinions from them. He had given a general mathematical solution in the paper. He pointed out that there was a certain resistance which was best, as there could not be convolutions without resistance. There was no difficulty in signalling when a line was in good order. What was required was to adopt the resistance to the line at its worst normal state.

The following paper was then read:

TRANSPARENT CONDUCTING SCREENS FOR ELECTRIC AND OTHER APPARATUS.

BY W. E. AYRTON, F.R.S., PAST-PRESIDENT, AND T. MATHER, ASSOCIATE.

It is well known that electrostatic instruments require to be screened from outside electric disturbance in order that their indications may be correct; but it is not so generally recognised that instruments intended to measure small forces, such as certain types of electromagnetic voltmeters, delicate vacuum gauges, etc., are liable to give wrong readings from an electric attraction being exerted on the pointer, such as is produced by the glass cover when it is touched or cleaned.

There is on the table here a well-known type of gravity electromagnetic voltmeter, which may be found on the switchboards of many English and continental electric light stations. At the present moment its terminals are not connected with the electric light mains of the building, so that it should indicate zero pressure. Let me, however, but stroke the right-hand side of the glass cover with my finger, and the pointer, as you see, at once turns to 80 volts or more. Conversely, let the terminals of the voltmeter be connected with the electric light mains: the pointer should point to about 100 volts, for that, as you know, is the pressure supplied by the Westminster Company. The voltmeter appears to be indicating correctly, but, on stroking the left-hand side of the glass cover, the pressure, as read by the instrument, appears to suddenly fall to some 40 volts; and a similar effect is

Digitized by Google

produced if a piece of wash-leather or dry waste be used in place of the finger.

If, then, it is possible to cause this instrument to indicate at will 60 or 80 volts too high or too low, how impossible must it be or feel sure that the glass cover—which is, of course, maintained in a dry condition in a hot engine-room—has not been electrified by some accidental touch of the coat sleeve sufficiently to cause an error of 3 or 4 per cent. in the reading of this voltmeter!

We find that it is not merely with this particular type of voltmeter that an error can be produced by stroking or rubbing the glass cover, for other electromagnetic instruments that we have tried can also have their pointers deflected in the same way, but not to the same extent.

Nor, of course, is this source of error in any way connected with a voltmeter being an instrument constructed to measure an electrical magnitude, for it would equally exist if the glass were clean and dry and the controlling force remained of the same magnitude, no matter what was the quantity the instrument was constructed to measure. For example, on the table there is a vacuum gauge, the wheel-sector-pinion of which has been replaced with an Ayrton-Perry magnifying spring. This gauge is, no doubt, very sensitive, for you observe that the pointer moves even when I produce an extremely slight diminution of pressure by rotating the short length of indiarubber tube as slowly as I can; the change of pressure on pinching the tube, or even on dropping it, is indicated by the pointer. On the other hand, the pointer is of glass, and therefore is not suitable for being acted on by an electrostatic force; still, a stroke on the glass cover, as you see, causes the pointer to deflect through several degrees.

It has been known for a long time that it is possible to screen an instrument from such outside electrostatic disturbances by surrounding it with a metallic cage composed of wire or of strips of tinfoil. Such a method of screening, however, has the great disadvantage that it renders it difficult to observe the exact position of the pointer from a distance, for the wires or strips of tinfoil cover up the pointer more or less. We therefore thought of placing the pointer underneath the metallic dial of our electrostatic voltmeters, and of only allowing the tip to project through a slot in the dial plate. But this method we abandoned on trying it 18 months ago, for to make the screening good the visible part of the pointer must be reduced to a spot, and the exact position of this spot we found less easy to read at a distance of several feet than that of a long black line, which is the appearance of a pointer when it is visible along its whole length. This method of screening has, however, we understand, been recently adopted by a firm of instrument-makers.

We next considered whether it was not possible to make a perfectly transparent conducting screen, so that, while the electrostatic screening of the pointer should be practically perfect, the pointer and dial should be as easily seen as if the screen were not present. Our first idea was to make the glass cover double, and to insert between the two sheets of glass a layer of clear conducting liquid. Fearing, however, trouble from leakage of the liquid, or from the liquid becoming gradually turbid, and giving the dial a dirty appearance, we turned our attention to depositing films of solid matter on the inside of the glass cover or shade of sufficient thinness to be practically transparent, but with the solid particles near enough together to be conducting. We tried smoke, silver deposited in layers of various thicknesses, mercury vaporised and deposited, sal-ammoniac vaporised and deposited, etc., but we were quite unable to obtain in this way both transparency and electric conduction.

After a conversation with Prof. Boys, when discussing the problem that we were then engaged in solving, we commenced experimenting on varnishes with the view of arriving at a varnish which should be as hard and as transparent as clear shellac, but which, instead of being an insulator like shellac, should be a sufficiently good conductor to allow of the instantaneous production of an induced electric charge to balance the electrostatic action of any outside body. Glass plates were coated with gum, with coaguline, with the gelatinous electrolyte used in accumulators (composed of sodium silicate and dilute sulphuric acid), with isinglass dissolved in acetic acid, with gelatine dissolved in acetic acid, with isinglass dissolved in a mixture of acetic and sulphuric acids, and with gelatine dissolved in the same mixture. After much experimenting, we arrived at the following two methods of coating a glass cover or shade, which gives perfectly satisfactory results:

No. 1.—Dissolve ½oz. of transparent gelatine in 1oz. of glacial acetic acid by heating them together in a water bath at 100deg. C. To this solution add half the volume of dilute sulphuric acid, which has been prepared by mixing one part of strong acid with eight of distilled water by volume, and apply the mixture while still warm to the glass shade, which should be previously polished and be warm. When this film has become very nearly hard, apply over it a coating of Griffith's anti-sulphuric enamel.

Method No. 2.—Thin the gelatine solution, prepared in the manner previously described, by the addition of acetic acid (say, two volumes of acid to one of the solution), and after polishing the glass, float this thinned solution over the glass cold. Drive off the excess of acetic acid by warming, allow the glass to cool, and repeat the floating process, say, twice. Thin the anti-sulphuric enamel by the addition of ether, and float it over the gelatine layer applied as just described. Expel the ether by heating, and apply a second layer of this thinned anti-sulphuric enamel.

With experience, such as Messrs. Elliott and Messrs. Paul have at length acquired after much practice, a layer can be applied, either according to method No. 1 or No. 2, so that, when finished, it is quite hard to the touch, and so transparent that it is only by looking at the glass plate obliquely that the presence of the varnish can be detected. It is also so conducting that when a P.D. of several thousand volts, alternating with a frequency of 200, is set up between the needle and inductors of one of our electrostatic voltmeters, the pointer, which is metallically part of the needle, is not visibly attracted by a metallic rod held just outside the glass close to the pointer, this metallic rod being electrically connected with the stationary inductors.

Without experience, however, it is somewhat difficult to apply the coating so that it is not either cloudy or a comparatively poor electrostatic screen, or both.

This second electromagnetic voltmeter—which, like the former, has been kindly lent us by Mr. Barley, of the Knightsbridge electric light central station—looks exactly like the other one, and, indeed, behaved exactly like the other one when we received it. It has, however, had a layer of our transparent varnish applied on the inner side of the glass subsequently, and you will find that you may rub the glass as much as you like, or even hold a rubbed stick of ebonite near it, without producing any effect on the pointer.

Again, these two clear glass shades, belonging to gold-leaf electroscopes, are one of them coated with our varnish, and the other not. Which is the uncoated one is at once apparent from the alteration produced in the deflection of the gold leaves when I approach a stick of rubbed ebonite near the lower part of the glass shade of the uncoated one, for no such change in the deflection is produced, as you see, when the ebonite rod is brought near the glass shade, which is protected by a layer of this varnish applied on the inside.

On the conclusion of the reading of this paper, it was decided to proceed with the perusal of the paper on "An Astatic Station Voltmeter," also by Prof. Ayrton and Mr. T. Mather, and to discuss both papers together. We shall give this paper in our next issue.

Mr. Mordey, who opened the discussion on the two papers, congratulated the authors on the features of the instruments that had been described. To show on a large open scale, at any particular part of the scale, was the most important feature brought out in direct-current reading instruments for a long time. Instrument makers had, as a rule, directed their energies to getting proportionalities in scales, but it was of more importance to have a very large and open scale. He hoped the authors would pursue their labours further and give them an alternating voltmeter with the same features. The instrument described was only suitable for direct currents which were not quite obsolete, but they would like to have the same features in alternating-current instruments. The authors were also to be congratulated upon the screen. He thought, perhaps, that he was the first to draw the attention of the professor to the necessity for something of the kind.

Mr. Crompton stated that the electrification of the glass was well known to every apprentice in central stations, as was also the way in which it was prevented. No inconvenience had, to his knowledge, arisen from the occurrence. It was rather an interesting thing to get up that phenomenon by warming up by means of the lamps. That would also not have happened if they had not had such a spring as the present. The defect was shown very strong in electrostatic instruments. They were greatly indebted to Prof. Ayrton. With regard to the other paper, he thoroughly agreed with the statement as to the requirements of a good station voltmeter. He opined that instruments already existed that many of them had carried out before, and some of the authors' improvements were not new. He had not seen the hand of the pointer, but he had drawings of it before him. That method had been used by his firm for some time past, as had also the clamping arrangement. The way in which he got out of the difficulty by using a moving coil had one serious defect—namely, it was costly. The Weston instrument was expensive, and it was a luxury to have one in a station. Commercially it would be found that the instrument described would be a costly one, and would not be within the reach of many of them. It was for that reason that they had been trying to make astatic instruments in a more simple way. At present the price of an instrument might be taken at £4, and he doubted whether the instrument referred to could be produced at that figure. They usually had one *good* voltmeter in a central station, and used it as a reference voltmeter. They had also a number of other voltmeters on the switchboard sufficiently close to the reference voltmeter for the purpose, and the errors from the reference voltmeter were known and noted. The error might sometimes be one per cent., or one and a-half per cent., and those at the switchboard were accustomed to make allowances for them. They found no difficulty in providing themselves with voltmeters, which were astatic within that limit of error. He thought that Prof. Ayrton would not be able to make very sensitive instruments with three coils, since the weight of the coils, etc., would necessarily render the instrument sluggish. With regard to open scales, he believed they had been made by different firms—Hartmann and Braun, for instance—and it was not a difficult thing to make an open scale as Mr. Mordey had suggested for alternating currents.

Prof. Ayrton, in reply to the discussion, said that Mr. Mordey was not correct in stating that he was the first to direct his (the speaker's) attention to this electrostatic action. With regard to Mr. Crompton's remark that it was only necessary to touch the voltmeter with the finger to rectify the deflection, it was a curious fact that a central station engineer had just informed him that such an action caused a greater deflection. The clamping devices had been used for three or four years in connection with their electrostatic voltmeters. Mr. Crompton was wrong about permanent magnets producing a sluggish instrument.

BOUND VOLUMES.

Vol. XII. of new series of "THE ELECTRICAL ENGINEER" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

THE TRAMWAYS INSTITUTE.

The occasion of the meeting of the Tramways Institute at Manchester may be taken to express regret at the very little progress electrical traction for tramway work is making in this country. The reason is not far to seek, but if any progress is to be made at all this reason must be well understood. In the first place, although the various managers have been shown by figures, statistics, and argument that electrical traction ought to pay, nothing has been said that convinces them as to its commercial practicability. They ask for proofs obtained from English lines, and these have yet to be given. The success of such traction on the South London Railway and at Liverpool is no proof that it will be successful on ordinary tramway lines. With South London it was Hobson's choice; with Liverpool, the case was not much different. All tramway managers are now awaiting Mr. Dickenson's paper on the working of the South Staffordshire lines—a paper which, we believe, will be presented to the Institution of Civil Engineers. Even if Mr. Dickenson succeeds in convincing the most sceptical as to the value of electricity, that will not induce managers to be very eager in taking up this kind of traction. Assuming, then, that figures are forthcoming which will definitely prove the practicability and cheapness of electric traction from the managerial point of view, there is still something to be desired. A tramway line in operation is fully equipped. Altering from horse to electric traction means the expenditure of additional capital, and the question at once arises, Will the increased expenditure bring increased returns upon the total capital expenditure? If it does not, what is the advantage of the change? If it does, the advantage is at once seen, and conviction of tramway interests on this point will soon put the required capital in the hands of managers. If a line does not now pay, the question will be somewhat different, and assume the shape of, Can it be made to pay by the alteration? The inability to pay dividends is generally from lack of passengers, and it is difficult to see how one form of traction will increase the number of passengers to any large extent. While, then, we regret the want of progress in electric traction in this country, we cannot be blind to the reasons which have made tramway managers cautious. From the humanitarian point of view, horseflesh in traction work should be abolished; but nowhere in the world's history have commercial undertakings been carried out from this point of view. No one who understands horses can for one moment ignore the fact that traction work is perhaps the most killing that horseflesh is subjected to, and would gladly see inanimate materials used in its place. Those, like us, who have advocated and do advocate the use of electric traction, advocate such use because from figures put before us, from our knowledge of the possibilities of electricity, we firmly believe that its use would in most cases where it is proposed lead to increased returns, the increase being proportional to or even greater than indicated by the

Digitized by Google

increased capital outlay. Only would this be the case, however, when the installation was properly designed and economically managed. We have always considered that the lighting station should also be the power station, as in many cases this would be an immense advantage to both parties. The over-lapping time would have to be arranged for in the station working, but we believe the economy would be greatly in favour of power and light from one roof rather than from separate establishments. Little straws tell the way the wind is blowing. And the mere fact that tramway people are getting more and more desirous of information about electric traction shows that they are beginning to feel an increased interest in the matter. Although not in this country, it is a significant fact, and will not be without weight here, that Brussels, which long since tried and rejected certain forms of electric traction, has again returned to that love, and probably before the end of the month will have the electric cars in full work. The tramways there are through broad boulevards, and the trial this time is to be by means of an overhead system. The wires are not unsightly—in fact, we doubt if ordinary passers-by would notice them so much as they do telegraph or telephone wires. If, then, a city given up to pleasure has no æsthetic uproar against overhead wires, we do not see why the examples of Leeds and South Staffordshire should not be followed in similar situations. Leeds is mentioned not because it offers a good example of electric traction prosperity, but because the system is overhead, and is used just at that one part of Leeds which possesses the greatest natural attractions. The district around Roundhay Park is naturally pretty, yet we have heard no resident complain, but rather they have expressed thankfulness that the overhead system existed. To sum up our points: managers must first be satisfied on the money question; those who control old lines must be further satisfied that a new expenditure will bring in commensurate returns; and lastly, that overhead systems are not objected to in places wherein they have been tried.

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

THE HERMITE PROCESS AT WORTHING.

SIR,—With reference to Dr. Kelly's report on the above, which you noticed in your last issue, permit us to point out that in our opinion the samples submitted to Drs. Klein and Dupré were not fair samples of the treated sewage, and that our view was supported by several members of the Worthing Town Council at their meeting last Tuesday. As a consequence of this feeling, the Council decided to consider the report as confidential, and not to adopt it or print it till it was confirmed by the investigations now being undertaken by the British Institute of Preventive Medicine. Unfortunately, Dr. Kelly had on his own responsibility allowed a large number of copies of the report to be distributed throughout the country. As you have given publicity to the report, we rely on your sense of fairness to give equal publicity to our protest.—

Yours, etc.,
PATERSON AND COOPER.

London, April 9, 1894.

OBITUARY.

The death has just taken place at Saratoff of M. Paul Jablochkoff, who was born at Serdobsk (government of Saratow) in 1847. The deceased, who belonged to a distinguished family, was appointed director-general of the Moscow-Koursk telegraph lines in 1871. While occupying this position he became deeply interested in the subject of electric lighting. In the following year M. Jablochkoff lighted by means of an arc light the track on the Moscow-Koursk section in front of the locomotive hauling the Imperial train on the occasion of the serious outbreak on the part of the Nihilists. The failures met with induced him to make improvements in the apparatus used. Since 1875, when he withdrew from the Imperial Telegraph Service, he devoted his time to the development of science. In 1876, M. Jablochkoff proceeded to Paris, and was subsequently sent to London to represent M. Bréguet at an exhibition of scientific apparatus. Returning to Paris, he made a long series of experiments, which resulted in the production of the Jablochkoff candle, and which gave a great spurt to electric lighting. In 1878 the Avenue de l'Opera, at Paris, was lighted by Jablochkoff candles, and the system soon extended to Rome and to London, the Thames-embankment being so illuminated. In reference to this, Major Flood Page writes as follows to the *Times*: "There is no doubt that he did a great deal in directing the attention of the very small body of electricians in 1876-77 to the practicability of electric lighting, and much credit is due to him for his original work and the advance he made. For some time his electric candle held its own, and was undoubtedly the best system then in existence; it is still in use in Indian mills and many other places. In spite of the fact that he was supported in St. Petersburg by an illustrious personage, this clever Russian officer was not a successful man, as we men count success. Nevertheless, that St. Petersburg, which was behind the other capitals in the use of gas, and Moscow, which was not lighted by gas till 1866, have their central electric stations, and palaces, houses, and streets electrically lighted, is in no small measure due to the interest taken in M. Jablochkoff, and the impetus given to electrical advance in Russia by his original work. Like many inventors, he was very sanguine, and was, I am afraid, a very disappointed man; his works at St. Petersburg were large and well planned, but when, some years ago, I saw them he was working hopefully and bravely, but under financial and other difficulties. It can hardly be denied that M. Jablochkoff was one of the ablest and most original of the band of practical electrical pioneers." M. Jablochkoff took out patents for various inventions, and his death is much regretted.

ELECTRIC TRACTION ON LONDON RAILWAYS.

BY FRANK B. LEA.

Everyone at all interested in the development of electric traction must feel considerably pleased at the success which has attended the first year's working upon the Liverpool Overhead Railway, the details of which may be gathered from the extremely interesting and valuable papers lately read before the Institution of Civil Engineers by Messrs. Greathead, Fox, and Parker, the responsible engineers for this line. This feeling of pleased satisfaction may well be intensified on remarking the way in which the investing public has shown practical monetary support during the past few weeks towards such electric railway projects in London—viz., the lines between Waterloo and the City, and Charing Cross and Hampstead—as have crystallised sufficiently for the purpose. These lines, it will, moreover, be remembered, are based on the principles adopted for the City and South London Railway—not at present a very great financial success, but doubtless offering full justification for its existence as a pioneer line. If it were possible to plan and execute a line or lines in London after the model of the Liverpool Overhead system, the smaller capital expenditure as compared with that required for underground lines would

Digitized by Google

naturally prove a great incentive to their immediate development. It is with the idea of examining into this question, or rather the possibilities of utilising for electric traction the railways at present worked by steam power, that this article is written.

The entire electrical equipment of the Liverpool line is stated to have cost about £80,000, and proves capable of operating a three-minute service on a double line about six miles long. Such an amount is considerably less in proportion than the expenditure upon rolling-stock alone for a line similar to the Metropolitan or Metropolitan District: and the question may therefore very well come up for treatment as to whether we might not secure important developments in electric traction at comparatively small outlay by utilising the surface and other lines already built, whilst at the same time pushing forward with all good will the new underground projects which will serve to complete the network around and through London.

Electric railway traction appears—in its present stages, at any rate—to be particularly and pre-eminently suitable for what may be called a "glorified tramway" service; that is, the greatest working economy and efficiency may be obtained on lines where there is a constant stream of light traffic at short intervals, where the trains run—as on the City and South London and the Liverpool Overhead—to and fro between two terminal stations, like a weavers' shuttle, or else continuously round a circle. Now, it is tolerably certain that the average Londoner, although he may think himself well acquainted with the ways and means of transit in London, would feel considerably astonished at the number and importance of existing railway services in the Metropolis which partake of this character, and which might, so far as that is concerned, appear to present a suitable field for the use of electric working.

There is, however, at least one fundamental difference or distinction between the electric railways already established and the steam railways thus suggested, which has a most important bearing upon the possibility of electric traction ever coming into use on the latter. The electric lines are isolated absolutely; they each run between fixed points and make no connections whatever for traffic purposes with adjacent railways. There is, of course, no serious objection to their doing so. It is simply a fact that at present traffic is confined solely to the lines in question, without interchange to other lines. When, however, we come to examine the steam railways where "shuttle" or circular traffic is to be found, the numerous junctions and connections with other lines involve so much interweaving of trains that the possibility of electric working becomes somewhat questionable, for reasons which may be detailed later on.

There are, roughly speaking, five great railway systems in the Metropolis upon which the shuttle or circular form of traffic may to a greater or less extent be found. Of these, naturally the most important section comprises the underground lines—Metropolitan and Metropolitan District—so far as the inner and outer circles are concerned, with, perhaps, one or two of the short extensions. Plenty has, perhaps, already been written upon the question of working these lines by electricity, and a great deal has been publicly said with regard to it, though apparently not enough to effect any real good in so desirable a direction. The financial difficulties involved appear to be too great for those now in authority to overcome, the condition of the lines being anything but favourable for obtaining and spending more money even upon improvements.

Assuming, however, that these difficulties, under other conditions, would not prove in any way insuperable, it can only be said that there is a crying necessity for the use of electric working on these lines. The present foul atmosphere alone would be sufficient reason for the change, whilst so far as the circle and shuttle trains are concerned, to work these by electricity would, if we may judge from results at Liverpool, effect considerable economy in time, labour, and, therefore, money. Is it, however, possible or practicable to work this traffic in such a manner whilst at the same time allowing steam-driven trains from other lines to exercise running powers, as they now do, upon the lines proposed to be operated electrically? Taking, for instance, the Inner Circle alone, besides the Circle trains, there must be accommodated traffic from the London and North-Western Railway, which runs a service from Broad-street to the Mansion House, *vid* Willesden; the Great Western Railway service between Aldgate and the Mansion House, *vid* Addison-road; the District service between New Cross, Richmond, and Wimbledon; the Metropolitan trains between Aldgate, Hammersmith, and Richmond; besides traffic from the lines running out to Acton, Ealing, and Hounslow; and the Outer Circle trains.

So far as the permanent-way is concerned there should be absolutely no obstacle whatever of any serious nature to the running of ordinary steam-driven trains upon electric lines; and the question of persuading *all* the companies involved to change or modify their rolling-stock need not, therefore, be raised at the outset. Much good might be effected by withdrawing the steam locomotives on the Circle trains alone, at the outset, leaving the remainder of the entire system to be changed or converted as opportunity may offer. Apparently, however, the irreconcilability of the two main interests involved—viz., the Metropolitan and District Railway Companies—is so great that nothing but strong pressure from the shareholders upon the respective directorates will ever effect the much-desired change. This, however, is by the way. An obstacle to the introduction of electric working of more importance even than the alterations required in the permanent way, etc., is the impossibility in many cases of running more trains upon certain lines already overcrowded with traffic. It has already been stated that the chief advantage of electric working lies in its economy when used for light traffic with short headway; but since the conditions of block signalling impose a practical minimum of time between trains, it follows that as soon as this limit is reached the running of more trains would simply lead to incessant delays or signal stops, and an enormous waste of power on the line in constantly starting and stopping between, as well as at, stations. There seems little doubt that automatic electric signalling, such as that adopted on the Liverpool line, would allow of a much shorter headway between trains than the usual method of hand-signalling; but there also seems little doubt that the Board of Trade would regard as quite impossible the use of such a system for lines upon which trains from outside companies possess and exercise running powers.

If London resembled New York, and were provided with a system of isolated lines—overhead or underground—there would be no difficulty at all in the matter from a technical point of view; and the operation of such a system by electricity would doubtless prove both efficient and economical. As it is, the Metropolis has been burrowed through and through in half-a-dozen places with lines, not only interconnected, but each and all joined up for traffic purposes with the great trunk lines radiating outwards. And most valuable connections these are, more especially for goods traffic, though, as we shall see later on, they serve in no small degree for passenger transit also.

(To be continued.)

THE USE OF SMALL ELECTROMOTORS.

Mr. W. Rechniewski writes in *L'Electricien* on the subject of the employment of electromotors in towns. He states that although the use of electromotors is becoming more and more frequent, the development thereof in towns is not what it ought to be. The causes are various and have often been discussed. The principal rival to the electromotor for small power in towns is the gas-engine. If the site is not of great importance, the price per horse-power hour settles the selection of the motor. It is seldom that the motor is wanted to work to its full power, or all the working day.

Apart from theory, it is as well to give a concrete fact. A Paris manufacturer adopted an electromotor of 4½ h.p. instead of a gas-engine of equal power. The difficulties were considerable. The motor had to work at a voltage of 440 volts and at 700 revolutions only, intermediary shafting having been found inadvisable.

Digitized by Google

Mr. Rechniewski gives the following figures of the expense per hour for a 4½-i.h.p. gas-engine:

	Running empty.	Full load.
(1) Gas consumed:		
1,800 litres per hour	·54f.	—
2,400 „ „ „	—	1·35f.
(2) Oil	·12f.	·12f.
(3) Maintenance	·13f.	·13f.
(4) Redemption in 10 years and interest at 5 per cent.	·199f.	·199f.
Total	·989f.	1·799f.

For the electromotor receiving current at ·45f. per 736 watts, the following results were obtained:

	Running empty.	Full load.
(1) Energy consumed:		
350 watts at ·061	·213f.	—
3,900 watts at ·061	—	2·379f.
(2) Oil	·001f.	·001f.
(3) Maintenance	·020f.	·020f.
(4) Redemption in 10 years and interest at 5 per cent	·099f.	·099f.
	·333f.	2·499f.

To sum up, the expenses per hour were:

	Running empty.	Full load.
Gas-engine (at 30c. per cubic metre)	·989f.	1·799f.
Electromotor (at 45c. per 736 watts)	·333f.	2·499f.

Consequently at full load the gas-engine is more economical. But as in most cases the power is only used to the extent of about 66 per cent. of the full output of the motor—the electromotor is preferable.

ELECTRICITY METERS.*

BY R. P. WILSON.

In this paper great care has been taken to eliminate as far as possible the historical element, and while the author is anxious to give unsuccessful inventors every credit for their efforts which have largely assisted in the production of the few meters which may be said to be commercially alive at the present day, he has confined himself to the description of the few that represent the survival of the fittest. When the system of charging for electricity at so much per lamp per annum was tried it was found to result in endless dissatisfaction, and now no "undertakers" would dream of charging, except under very special circumstances, and no "consumer" would dream of paying, for his current on the contract system. As specified by the Board of Trade, the duty of an electricity meter is to ascertain and integrate the quantity of electrical energy (E × C) supplied to an installation. Many engineers, however, are content to use ampere-hour meters, and to assume that the voltage on their mains is constant; whereas the author is given to understand that in some cases this cannot be relied on even with that degree of certainty which has been attained by gas lamps when there is water in the pipes.

The earliest form of meter used was that designed by Edison, in which a portion of the current to be measured passed through a cell containing a solution of sulphate of zinc in which are immersed a positive and negative electrode, both of zinc, the current being measured by weighing the plates at intervals, and thus ascertaining the weight of metal transferred from one plate to the other. After each measurement or meter reading the poles are reversed, and the metal deposited is transferred back to the original positive plate, which now becomes the negative electrode of the cell. It was found, however, that the back E.M.F. of the cell varied with the temperature, so that it became necessary to compensate for the error thus introduced. This is effected by inserting in series with the cell a small copper wire resistance whose value varies with the temperature, whereas the resistance of the cell varies inversely as the temperature, so that the resultant resistance remains practically constant. The larger part of the current passes through a German-silver resistance, forming a shunt across the cell—in fact, only ·025 of the whole current is measured, so that any error in the chemical balance used to weigh the amount of metal deposited is multiplied enormously; and though this is a serious objection to the principle, this meter is still very largely used abroad, but only to a very moderate extent in this country. A further difficulty is that the electrolyte in the cell is liable to freeze; to obviate this, a double metal strip, consisting of two metals whose temperature coefficients are different, is introduced. The two metals are fixed together at both ends, and supported at one end only; under the other end is an adjustable contact screw, so arranged that when the temperature falls below a predetermined point, and alters the curvature of the double metal strip, it makes contact with the screw, and by doing so completes the circuit of an incandescent lamp, the heat of which is sufficient to maintain the necessary temperature in the meter case. In cold climates this is, of course, an insuperable objection to the use of the meter, as the station would be called upon to supply current for a number of lamps for which they would, of course, receive no revenue.

Another form of electrolytic meter was devised by Messrs. Lowrie, Hall, and Kolle for use on an alternating current, and consisted of an accumulator in series with the customer's transformer. The effect of this is, of course, to add two volts to the E.M.F. of the positive side of the alternation, and to diminish those of the negative side by a similar amount; the whole current to be measured passed through the accumulator and the electrolytic bath was acted on by the two volts passing continuously in one direction, the current passing through it, and consequently the metal deposited, being, of course, proportional to the lamps alight. It will be seen that if any lamps are left turned on when the primary of the converter is switched off, the accumulator continues to discharge through these lamps, and the electrolytic action in the meter cell continues. The necessity of using a chemical balance to ascertain the consumption of energy in a consumer's premises is very inconvenient, and the consumer himself is not always provided with that childlike faith which is so essential when he cannot take his own meter readings. It is now an axiom that meter dials shall be so constructed that they do not require interpretation by an expert. The above are the only two electrolytic meters which have been used commercially; others have been invented, but their existence has been ephemeral.

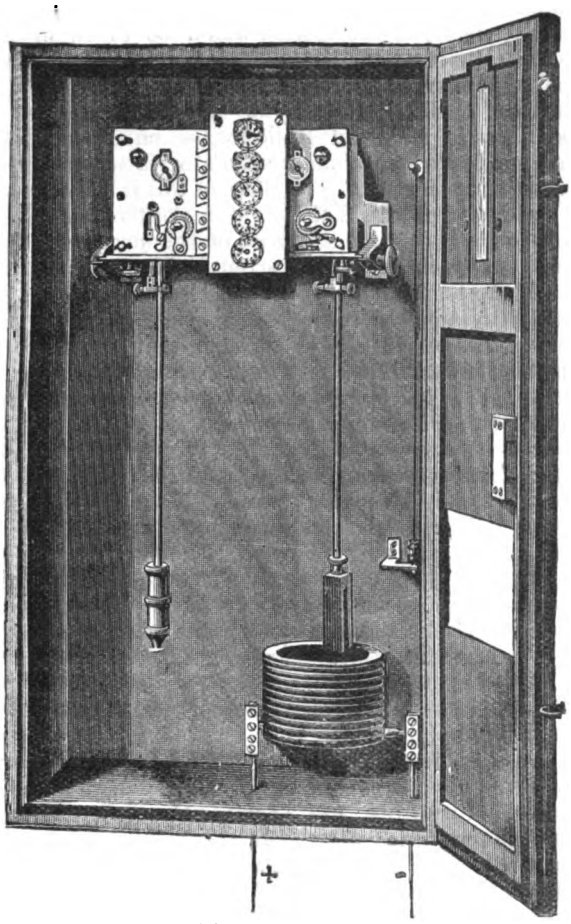
The meters most largely used in this country now are the following: (1) the Aron ampere-hour and watt meters, direct and alternating; (2) Thomson-Houston wattmeter, direct or alternating; (3) the Shallenberger ampere-hour meter, alternating only; (4) the Ferranti ampere-hour meter, direct current; (5) the Chamberlain and Hookham direct-current ampere-hour meter. This order approximately represents the extent to which the various types are in use.

(1) *The Aron Meter*, designed by Dr. Aron, of Berlin, was the first practical meter exploited, and many a central station owes a great deal to Dr. Aron. This meter is of the independent motor type, and has gone through many modifications. It consists now of two clocks mounted together on one common base, each driving one wheel of a differential gear; between these two bevel wheels is a third, which gears with both, but which, being free to revolve on its axis, communicates no motion to the dials so long as the two clocks are absolutely synchronous. Of the two pendulums, one is provided with a weight in the ordinary way, and its only duty is to beat seconds with constant regularity; the other is provided with a weight in the form of a permanent magnet in the direct-current ampere-hour meters, or a fine wire coil in the case of the wattmeters. In the first case, the permanent magnet (which beats seconds) normally oscillates over the end of a solenoid in series with the circuit whose consumption is being measured, and the value of each of its beats varies in proportion to the current passing through the solenoid. In the second case (the wattmeter), the permanent magnet is replaced by a fine wire coil oscillating through a solenoid; the resultant effect on the pendulum is proportional to

* Paper read before the Northern Society of Electrical Engineers, April 9, 1894.

Digitized by Google

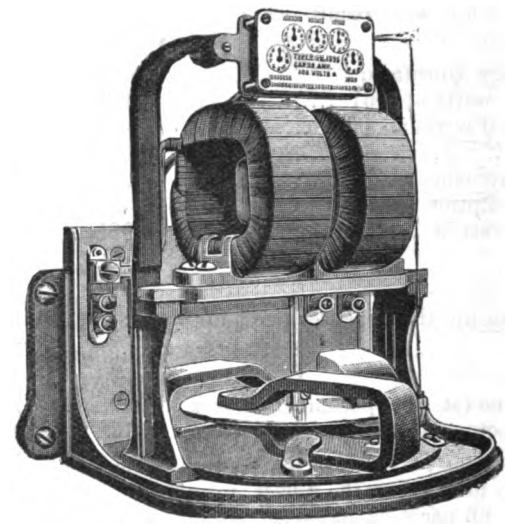
$C \times c$, or $C \times E$, because c varies, of course, with the E.M.F. The principal difficulty these meters present is in keeping the clocks synchronous. Several modifications have been introduced from time to time to effect this; the one most frequently used consists of a loose thread attached to both pendulums carrying a small weight in the middle. But the difficulty has been entirely obviated in a modification introduced by Mr. Miller, of the Kensington and Knightsbridge Company, in which the second clock is dispensed with entirely. The one clock drives a copper disc whose speed is retarded by the current in the series coil before which it revolves. Mr. Miller is also responsible for another very ingenious modification of this meter, which, by making its curve the same going backwards or forwards, enables it to be used to ascertain the efficiency of a secondary battery, and practically the energy it contains at any period of its discharge, by enabling the meter to reduce its reading during the discharge by revolving in the opposite direction.



The Aron Meter.

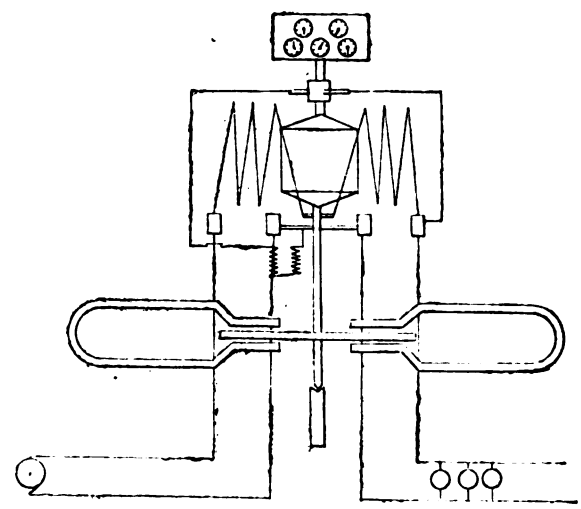
Before leaving these meters it may be well to draw attention to the Oulton-Edmondson meter, which, although not very largely used in this country, has many points in its favour. Like the Aron, it consists essentially of two pendulums vibrating in unison until interfered with by the retarding influence of the series coil, but the mechanism driving these pendulums is electrical throughout; their unison being maintained by communicating the vibrations of one to the other by means of a rigid bar in place of the thread and weight referred to above. The total consumption of each of these meters is two watts per hour, and they have some advantages over the Aron in that they do not require winding or an expert watchmaker to set them up and keep them in repair, and their pendulums do not vibrate except when current is being used.

(2) *The Thomson-Houston Wattmeter.*—This instrument is one whose invention has been claimed by a large number of professors and others, but was presumably originated practically by Prof. Elihu Thomson. It consists of a motor wattmeter whose armature has a vertical shaft extending through the series coil top and bottom, and communicating with the registering mechanism above, and carrying a copper disc at the bottom. This disc revolves between the poles of three permanent magnets. This combination forms a dynamo with a short-circuited armature whose Foucault currents, by reacting on the field magnets generating them, produce a retarding effect on the armature shaft which is proportional to its speed, so that the ultimate speed of rotation is directly proportional to the torque represented by $C \times c$. This is, of course, only correct assuming that the effect of friction has been eliminated. To do this, the amount of friction has been reduced to a minimum by having a jewelled bearing mounted on a spring at the bottom, and a guide only at the top; and its effect, which may be taken to be constant for all speeds, has been counteracted by allowing the armature



The Thomson Meter.

current to pass through the series coil first, so that at all times the initial torque is such that the friction error is negligible. This meter may be used indiscriminately on direct and alternating currents as the added resistance in series with the armature is a very large proportion of the whole, and is wound non-inductively, so that up to about 130 periods per second the self induction may be neglected, as a matter of fact, in practice, if it is found that the difference in the constant of the meter when used on a direct current and on a circuit of 130 periods is less than 1 per cent. They are also constructed for three and five wire circuits. The connections are respectively as follows:

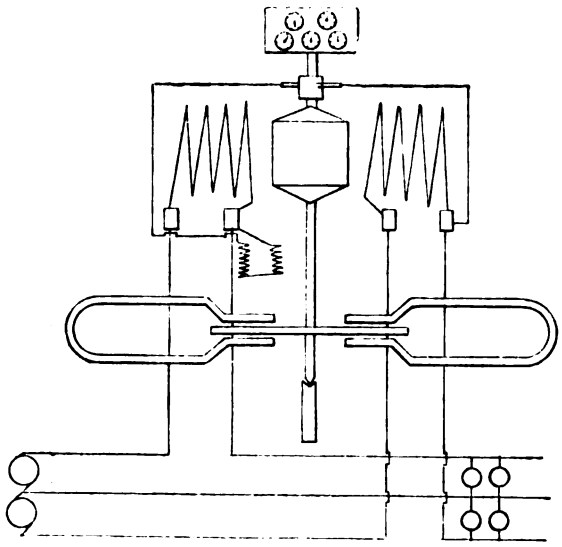


Thomson-Houston Meter—Connections on 2-wire Circuit.

The action of the former is simple enough. Each of the series coils exerts a torque corresponding to $C/2 \times c$, but it must be remembered that c is $= 200/r$, whereas C is $= 100/R$. The five-wire meter is rather more involved, because it will be seen that the current in the coils B and C may be travelling in either direction. The result under any given circumstances may be best demonstrated by taking an example. Let total E.M.F. = 400 volts, and let us assume that the current in each of the five conductors is as follows: A 100, B 25, C 25, D 25, and E 25 amperes. The 25 amperes in B is opposing the meter's rotation in

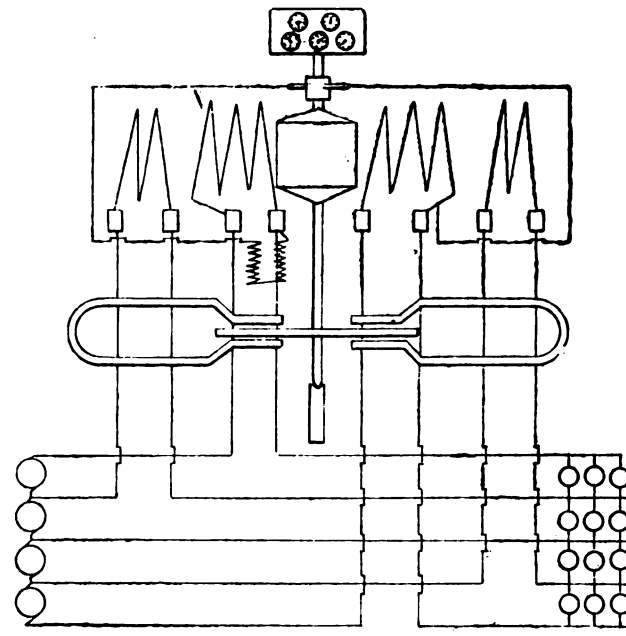
Digitized by Google

the direction of the torque produced by A C, D C, and E C, so that it will ultimately register (A C/2 – B C/1 + D C/1 + E C/2), c being, as before, proportional to the whole potential difference between A and E—that is to say, the total watts coming out of the station = (100/2 – 25/4 + 25/4 + 25/2) 400 = 25,000.

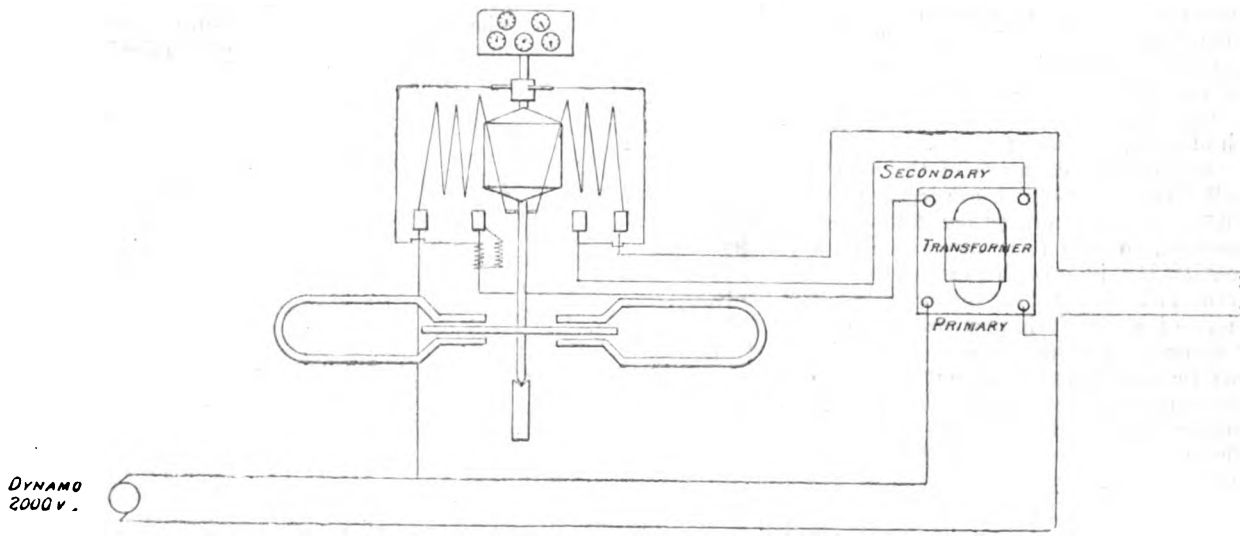


Thomson-Houston Meter—Connections on 3-wire Circuit.

sent out of the station, that Dr. Fleming's anticipations are very nearly realised. In a paper read before



Thomson-Houston Meter—Connections on 5-wire Circuit.



Thomson-Houston Meter—Primary of Alternating System.

Thomson-Houston Primary Meter.—This instrument is one with which most of you are already familiar, and consists of an ordinary Thomson-Houston meter, such as has already been described, having the series coils specially insulated to allow of its being used on a high-tension circuit. The volts for the shunt coil are reduced from 10,000 or 2,000, whatever they may be, to 50, by means of a transformer, and this combination, although claimed by several people, was originally suggested and used by Prof. Elihu Thomson to measure the true watts coming out of alternating-current stations so long ago as 1888 experimentally, and was put on the market commercially in 1889. The use of the transformer does not interfere with its accurate registration, for the reason that the current absorbed by the shunt coil is so small in proportion to the out put of the transformer that the lag in its secondary current is 180deg. behind the primary E.M.F., or, in other words, to all intents and purposes coincident with it: so that at any given moment C × c gives true watts, as the registrations are not those of the mean current multiplied by the mean E.M.F. The importance of this is so self-evident in a high-tension station, either with the transformers banked or in customer's premises, that it requires no comment; and it is interesting to be able to state from the actual experience of a large number of central-station engineers who are using these meters, to ascertain practically the ratio between the apparent and true watts the Society of Electrical Engineers in London, he stated that the apparent would be about 14 per cent. higher than the true watts; as a matter of fact, in practice this figure varies, but it is generally in the region of 12 per cent.

(To be continued.)

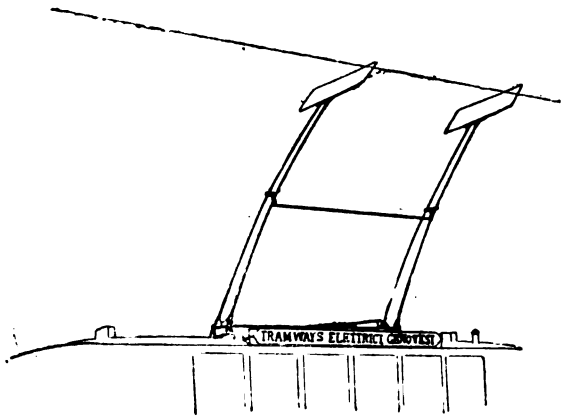
OVERHEAD CONTACT ARRANGEMENT — GENOA ELECTRIC TRAMWAY.

Last week we gave (see page 403) some details of the electric tramway carried out in the spring of 1893 by Messrs. Siemens and Halske, of Berlin, along one of the main thoroughfares in Genoa, and an account of a Swiss firm which had obtained concessions for this development in electric traction locally.

As, however, the particulars there given were perhaps insufficient for the purpose of presenting an accurate account of the special features worth noticing in connection with the line and system employed, we now append an illustration to show the type of overhead contact employed, from which it will be seen that a wide departure from the ordinary "trolley" system has been taken. The actual travelling contact consists of the upper side of a rectangular frame supported by two tubular uprights. It is formed of

Digitized by Google

a special metallic compound, and is easily renewable when worn. It presses against the *under* side of the overhead conductor or line wire (not the *top* side, as we were made to say last week by a printer's error), strong spiral springs being used to keep the surfaces in contact. These springs are attached by one end, as shown, to the bottom of the uprights, the other end being fastened to the roof frame of the car. Two contact bars and frames are provided for each car, mounted on the roof, as shown in the illustration.



The advantages claimed for this method of drawing current from the line wire are, briefly, the following. In the first place, a much greater degree of reliability in maintaining contact is secured as compared with the "trolley" system, and obviously there is not the same danger of continually jumping away when the car oscillates endwise—or "teeters," as the Americans say. Moreover, the contact bar is made of a length almost equal to the width of a car, so that ample swing is allowed for.

In the second place, much of the overhead straining or pull-off wires are rendered unnecessary at curves since the conductor or line wire need not follow the rounded curve of the rails, but can form a chord across, since the length of contact bar is enough to preserve contact, although at different points as the car moves round. This advantage becomes of no small importance when it is remembered that in many cases the only serious objection to the use of electric tramways on the overhead-wire system lies in the ugly and unæsthetic appearance of the numerous wires—conductor and supporting—at the curves. Any method which avoids this objectionable feature deserves strong recommendation.

POLYPHASE TRANSMISSION.*

BY CHARLES F. SCOTT.

(Concluded from page 410.)

Advantages of Three Phases.

In transmission it has been recently emphasised by a good many people that the single-phase system and the two-phase system require the same weight of copper, and that the three-phase three-wire system requires 25 per cent. less for transmitting power under similar conditions, with the same maximum E.M.F. This places an advantage on the side of the three-phase system, which in many cases is of very considerable importance. The aggregate advantage, however, is greater than 25 per cent. A two-phase system laid out for the greatest economy requires that the interest on the cost of conductors shall equal the cost of the power lost. If the three-phase system be substituted the loss may remain the same, and the copper will cost 25 per cent. less. This does not give the best relation between cost of copper and loss of power, so that a more economic adjustment is evidently possible.

It has also been shown that the self-induction of a three-phase three-wire circuit for transmitting under similar conditions of E.M.F. is only 57 per cent. of that which is incident to the two-phase four-wire circuit. When the power factor is high, the effect of self-induction of line upon regulation varies approximately as the square of the counter E.M.F. The drop due to the self-induction of a three-phase circuit is therefore only about one-third of a single-phase or two-phase circuit. This is a second advantage for the three-phase system which is of great value. A further advantage of three wires instead of four wires is the reduced cost of insulators and pole construction, the reduced losses due to leakage, etc.

Advantages of Two Phases.

An important point of difference between the two systems is the effect of loading one branch of the system more heavily than the others, as is common in incandescent lighting. One of the statements which remain uncontroverted in Prof. Forbes's recent comprehensible and remarkable paper upon the "Electrical Transmission of Power at Niagara Falls," is in reference to the difference of regulation in dynamos for two-phase and for three-phase alternating currents. He gives the result of tests showing that the circuits of a three-phase generator differ greatly in pressure if they are not equally loaded, and states that, having considered these points, the directors of the company determined to reject the three-phase system. These results agree fairly well with tests which I have made. The relative regulation of the two types of machine depends very largely, of course, upon the character of the construction. Although it is not just to condemn one system because a certain construction is bad, yet the theoretical and practical tendencies toward the evil are largely removed by discarding the three-phase type.

If independent regulation of circuits is necessary, one circuit can be given the proper pressure directly from the dynamo, and the other circuits may be raised or lowered as may be required. This involves apparatus for regulating two circuits if the station be operated by the three-phase system, and only one circuit if the two-phase system is in use.

In a system where incandescent lighting is to be a prominent feature, or where load of any kind may be required upon one circuit and not on the other, the two-phase system has therefore a decided advantage in station regulation over the three-phase system. Another advantage of a two-phase circuit is that the load is separated into two divisions instead of three divisions, which is in general much simpler. A further advantage of the two-phase is in the reduction of potential for motors, Two transformers are sufficient in the two-phase system. whereas three transformers are commonly used in the three-phase system. The two transformers which would be required for small motors will cost considerably less than the three transformers which would be required on the three-phase system, and the loss in transformation will be much less, as there is not much difference in the cost of small transformers of slightly different sizes, and the large sizes are more efficient. The ease and simplicity of installation is also a gain for the two-phase arrangement.

A New System.

In considering the marked advantages of the two-phase system for distribution and of the three-phase system for transmission, it occurred to me that a combination of the two systems might secure the advantages of both in a combined system, and I have worked out a simple and effective method of accomplishing this result. It is well known that if two E.M.F.'s differing in phase be connected in series that the resulting E.M.F. will in general differ in value and in phase from either of its components. If two E.M.E.'s differing in phase 90deg. be connected in series, the resultant E.M.F. is represented in direction and magnitude by the hypothenuse of a right-angle triangle of which the two sides are the two component E.M.F.'s. Thus, in Fig. 14, if A O and O B are two E.M.F.'s at right angles, and these E.M.F.'s be connected in series, the resultant is the line A B of different phase from either of the components. It is a simple matter to so proportion the components that O B is equal to one-half of A B, as shown in the diagram. In a similar manner it is readily seen that the same E.M.F. O A may be combined with O C, which differs from it by 90deg. (but is equal and opposite to O B) in such a way as to give A C equal to A B, but differing in direction. B O and O C added together give B C. The

* Paper read before the National Electric Light Association, Washington

Digitized by Google

E.M.F. B C may, therefore, be combined with the E M.F. A O at right angles to it in such a way as to give additional E.M.F.'s A B and C A, which, in connection with B C, give three equal E.M.F.'s 120deg. apart. This is the relation of E.M F.'s on the three-phase system.

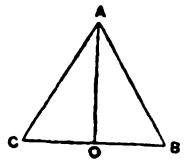


FIG. 14.

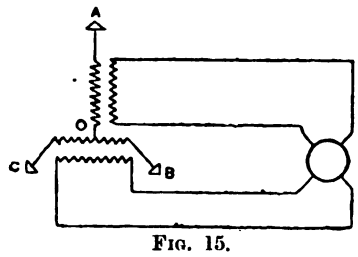

FIG. 15.

The application of this arrangement to transformers is illustrated in the accompanying Figs. 15 and 16. The

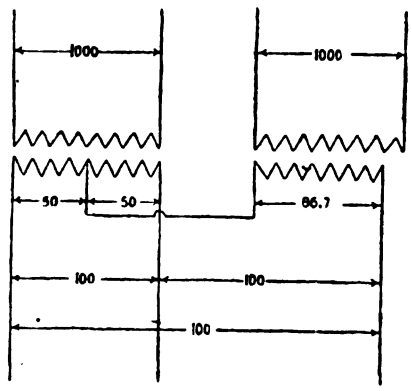

FIG. 16.

primaries of two transformers are connected to a generator giving two-phase current. The secondary E.M.F.'s, there fore, differ 90deg. One secondary is made equal to 100 turns, and a loop is brought out at its middle point, giving 50 turns at each side. The second secondary has 87 turns, which is approximately equal to 50 multiplied by the square root of 3. One end of the secondary circuit is connected with the middle point of the secondary of the first transformer, as shown, and the three free terminals will then deliver E.M.F.'s differing in phase 120deg. If the E.M F. on each primary be 1,000 volts, and on one secondary 100 volts, and on the other 87 volts, then the E.M.F. measured between any two secondary terminals will be 100 volts.

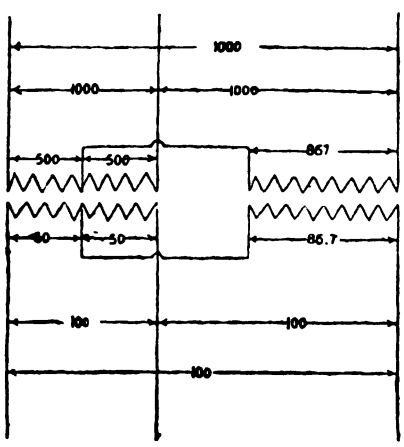

FIG. 17.

This three-phase circuit is adapted for operating three-phase motors. In a system of transmission, two-phase currents at the generator may be converted into three-phase currents, as shown in Fig. 18, and the windings may be such that the E.M.F. is raised for transmission. The currents are then transmitted by three phases, effecting economy in copper. At the other end of the line a similar arrangement of transformers may be used for converting from the three-phase to the two-phase system. The two-phase currents may then be used for the operation of two-phase motors, or the circuits may be independently loaded with lamps, or otherwise. If lamps be placed on the transformer, which supplies directly from its two terminals, the transmission is directly from the generator, without affecting in any way the other circuit, as the generator terminals are connected directly to the first primaries, and the secondaries of the raising transformer are connected directly to the primaries of lowering transformer, and the current from this is taken directly to the load. On the other hand, if the other circuit be loaded, the action here will also be on its own generator circuit without affecting the first. The current from the raising transformer in this circuit passes to the middle of the secondary of the other transformer, where it divides and flows in parallel through the two parts of the coil and two of the lines. As one-half of the current flows through each part of the secondary coil in opposite directions, the self induction is completely neutralised, and the transformers in this circuit are independent of the operation of the other circuit. It is to be noted that under this condition the line E.M.F. delivered by this transformer is only 87 per cent. of that delivered by the first transformer. The lower E M.F., however, is compensated for by the fact that the current on one side is passed through two of

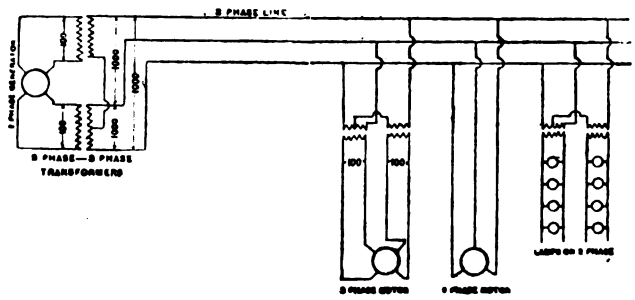

FIG. 18.

the lines in parallel, thus reducing the resistance of the circuit and compensating for the slightly lower E.M.F.

The effect upon the regulation of the generator when two-phase circuits at the end of a three-phase transmission line are independently loaded is found, both by theory and test, to be the same that prevails when the load is placed directly upon the corresponding circuit of the generator. A modification of this system is found in the arrangement where the three-phase current is produced in the generator and transmitted over three wires to the reducing transformers. These transformers may be arranged as described for producing two phases (Fig. 19). Loads may be placed upon either of the two-phase circuits, and practically the same regulation in the generator will result that would have resulted if the generator itself had been wound for two phases and one of these circuits loaded. In this way it is possible to place lighting load upon a three-phase

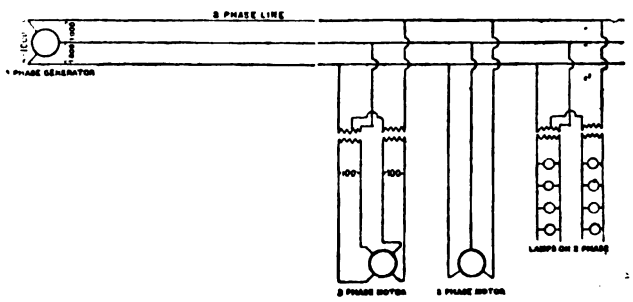

FIG. 19.

generator in two instead of three units, and to avoid the bad regulation in the generator due to unequal loading.

A similar arrangement of two transformers may be used for converting three phases of one potential into three phases of another potential. This arrangement is shown in the accompanying Fig. 17.

The efficiency of two transformers arranged for converting from two-phase to three-phase is reduced below that when working independently on ordinary loads by an insignificant amount. If the efficiency in ordinary working is, say, 97·5 per cent., it would be reduced to 97·4 per cent. in converting from one number of phases to the other.

Digitized by Google

The Tesla polyphase system, in which the largest electrical enterprises are seeking a realisation, adapts itself with marvellous facility, not only to all branches of electrical industry, but also by the transformation of its phases to the utilisation of three phases for gaining the highest economy in transmission, and of two phases for securing the maximum advantages in distribution.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION'S STANDARD RULES FOR ELECTRICAL CONSTRUCTION AND OPERATION.

We reproduce below the standard code of rules* issued by the National Electric Light Association. These rules were revised and adopted at the seventeenth convention held at Washington on February 27 and 28 and March 1 and 2, 1894:

CENTRAL STATIONS.

CLASS A.—FOR LIGHT, HEAT, OR POWER.

1. These rules also apply to dynamo-rooms in isolated plants, connected with or detached from buildings used for other purposes. Also to all varieties of apparatus of both high and low potential.

2. The floors of central stations should be cleaned thoroughly at least once a week, and especial care taken that oil is not thrown from the machinery, as floors and machinery saturated with oil increase greatly the fire risk.

3. Oil, waste, and such supplies should not be kept in the loft or cellar, and where it is impossible to remove them to a separate building automatic sprinklers must be installed.

Generators or Motors.

1. Must be located in a dry place.

2. Must be insulated on floors or base frames, which must be kept filled to prevent absorption of moisture, and also kept clean and dry.

3. Must not be exposed to flying or combustible materials.

4. Must each be covered with a waterproof cover when not operating.

5. In no case must a generator be placed in a room where any hazardous process is carried on, such as the working-room of a cotton, jute, flax, woollen, or flour mill.

Care and Attendance.

1. A competent man must be kept on duty in the room where generators are operating.

2. Oily waste must be kept in metal cans, and removed daily.

Conductors.

From generators, switchboards, rheostats, or other instruments, and thence to outside lines, conductors:

1. Must be in plain sight.

2. Must be wholly on non-combustible insulators, such as glass or porcelain.

3. Must be separated from contact with floors, partitions, or walls through which they may pass by non-combustible insulating tubes.

4. Must be kept rigidly so far apart that they cannot come in contact.

5. Must be covered with non-inflammable insulating material sufficient to prevent accidental contact.

6. Must be ample in carrying capacity to prevent heating. (See capacity of wires table.)

7. Must be connected by splices or joints equal in carrying capacity to the conductors themselves, soldered to make them efficient and permanent.

8. Must be, when under floors or in distributing towers, placed in spaces ample for inspection and ventilation, and provided with special insulating covering.

Switchboards.

1. Must be so placed as to make it impossible to communicate fire to surrounding combustible material; accessible from all sides when the connections are on the back; or may be placed against a brick or stone wall when the connections are entirely on the face.

2. Must be kept free from moisture.

3. Must be made of non-combustible material, or of hard wood, filled to prevent absorption of moisture.

4. Must be equipped with bars and wires in accordance with Rules 1, 2, 3, 4, 5, 6, and 7 for placing conductors.

Resistance Boxes and Equalisers.

1. Must be equipped with metal or non-combustible frames.

2. All rheostats for controlling dynamos, motors, or devices for electric heating and cooking should be constructed entirely of non-combustible materials.

3. Must be treated as sources of heat.

4. Must be placed on the switchboard, or a distance of a foot from combustible material, or separated therefrom by asbestos or cement.

Lightning Arresters.

1. Must be attached to each side of every overhead circuit connected with the station.

2. Must be in plain sight.

3. Must be on the switchboard, or in an equally accessible place, away from combustible material.

4. Must be connected with at least two earths by separate wires not smaller than No. 6 B. & S. gauge.

5. Must be so constructed as not to maintain an arc after the discharge has passed.

Testing.

1. All series and alternating circuits must be tested every two hours while in operation, to discover any leakage to earth abnormal in view of the potential and method of operation.

2. All multiple arc low-potential systems (300 volts or less) must be provided with an indicating or detecting device, readily attachable, to afford easy means of testing where the station operates perpetually.

3. Data obtained from all tests must be preserved for examination by insurance inspectors.

CLASS B.—ARC (SERIES) SYSTEMS.

Outside Conductors.

All outside overhead conductors (including services):

1. Must be covered with some insulating material not easily abraded.

2. Must be firmly secured to properly insulated and substantially built supports, all the wires having an insulation equal to that of the conductors they confine.

3. Must be so placed that moisture cannot form a cross-connection between them, not less than 1ft. apart, and not in contact with any substance other than proper insulating supports.

4. Must be at least 7ft. above the highest point of flat roofs and at least 1ft. above the ridge of pitched roofs over which they pass or to which they are attached.

5. Must be protected, whenever necessary, in view of possible accidents to conductors or supports, from possibility of contact with other conducting wires or substances to which current may leak, by dead insulated guard irons or wires. Special precautions of this kind must be taken where sharp angles occur, or where any wires might possibly come in contact with electric light or power wires.

6. Must be provided with petticoat insulators of glass or porcelain. Porcelain knobs, cleats, and rubber hooks are prohibited.

7. Must be so spliced or joined as to be both mechanically and electrically secure without solder. They must then be soldered to ensure preservation, and covered with an insulation equal to that on the conductors.

8. The following formula for soldering fluid is approved:

Saturated solution of zinc	5 parts.
Alcohol	4 ,,
Glycerine	1 ,,

9. Conductors should not be run over, or attached to, buildings other than those in which light or power is being or is to be used, but on separate poles or structures always easily inspected.

Service Blocks.

1. Must be covered over their entire surface with at least two coats of waterproof paint, and so maintained.

2. Telegraph, telephone, and similar wires must not be placed on the same arm with electric light or power wires, and should not be placed on the same structure or pole.

INTERIOR CONDUCTORS.

All Interior Conductors.

1. Must be, where they enter buildings from outside terminal insulators to and through the walls, covered with extra waterproof insulation, and must have drip loops outside, preferably slanting upward toward the inside, and bushed with waterproof and non-combustible insulating tube.

2. Must be arranged to enter and leave the building through a double-contact service switch, which will effectually close the main circuit and disconnect the interior wires when it is turned "off." The switch must be so constructed that it shall be automatic in its action, not stopping between points when started, and prevent an arc between the points under all circumstances; it must indicate on inspection whether the current be "on" or "off," and be mounted on a non-combustible base in a position where it can be kept free from moisture and easy of access to police or firemen.

3. Must be always in plain sight, never covered, except in special cases, where an armoured tube may be necessary.

4. Must be covered in all cases with a waterproof non-combustible material that will adhere to the wire, not fray by friction, and bear a temperature of 150deg. F. without softening.

5. Must be in dry places kept rigidly apart at least 10in., except when covered (in addition to insulation) by waterproof, non-conducting, and non-inflammable tubing, which must be strong enough to protect the insulating covering from injury. Conductors thus placed may be run not less than 3in. apart, and be fastened with staples, under which are placed mechanically rigid insulating strips or saddles of greater width than the metal of the staple, by which possibility of injury to the tube may be prevented

6. Must be in damp places attached to glass or porcelain insulators, and separated 10in. or more.

7. Must be, when passing through walls, floors, timbers, or partitions, treated as in central stations under like conditions.

* *Notice.*—These rules are subject to amendments or alteration, and will be modified from time to time as experience and the exigencies of electrical development demand. All such changes shall receive the official sanction of the National Electric Light Association, and be given immediate publicity upon their adoption.

Digitized by Google

LAMPS AND OTHER DEVICES.

Arc Lamps.

1. Must be carefully isolated from inflammable material.
2. Must be provided at all times with a glass globe surrounding the arc, securely fastened upon a closed base. No broken or cracked globes may be used.
3. Must be provided with a hand switch, also an automatic switch, that will shunt the current around the carbons should they fail to feed properly.
4. Must be provided with reliable stops to prevent carbons from falling out in case the clamps become loose.
5. Must be carefully insulated from the circuit in all their exposed parts.
6. Must be, where inflammable material is near or under the lamps, provided with a wire netting around the globe and a spark arrester above, to prevent escape of sparks, melted copper or carbon.
7. Incandescent lamps in series circuits, having a maximum potential of 350 volts or over, must be governed by the same rules as for arc lights, and each series lamp provided with a hand switch and automatic cut-out switch; when lights are in multiple series, such switches and cut-outs must not control less than a single group of lights. Electromagnetic devices for switches are not approved.
8. Under no circumstances will incandescent lamps on series circuits be allowed to be attached to gas fixtures.

(To be continued.)

ELECTRIC RAILWAYS.*

The science of electricity is rapidly developing as an aid to locomotion, and though already a great deal has been done to demonstrate the practical use to which electrical power can thus be put, there is yet much room for future improvement. . . . The comparative cheapness with which tunnelling can now be carried out by means of the Greathead system has also given an important impetus to the underground electric railway as a promising enterprise. For example, the City and South London Railway, which has now been in working order over three years, cost rather under £300,000 per mile to construct and equip, compared with £1,000,000 per mile, the cost of the City lines of the District and Metropolitan Companies. The City and South London has really done a great public service, by demonstrating that electricity can be used as the means of efficiently working an underground railway. Unfortunately, it has not as yet been an altogether profitable undertaking so far as its shareholders are concerned, but of course, as a pioneer, it has had exceptional difficulties to overcome. It is, however, gradually improving its position from the investor's as well as the public point of view. Of course, the working of this line, since its opening in December, 1890, has been watched with great interest, and the experience gained thereby should prove of great benefit in the case of projected undertakings of a similar nature. It may be of interest to deal with some of the features of the City and South London Company, in view of the interest aroused in the investor's mind regarding electric railways. During the first year's working it carried 5,161,000 passengers, and ran about 350,000 train miles over its three miles of railway. In 1893 it carried 6,240,007 passengers, and ran 441,765 train miles over the same length of railway. The receipts increased from £39,201 to £44,526, and the net revenue from £8,908 for 1891, to £16,310, so that, in spite of a large increase in passengers carried and revenue earned, expenses declined considerably. The proportion of working expenses to gross receipts is still high, however. For the year 1893 expenses swallowed up 65 per cent. of the revenue. This contrasts with a percentage of 40 in the case of the Metropolitan, and 45 in the case of the District Company for working expenses. This higher ratio in the case of the City and South London compared with the old underground system is due to the smaller amount earned per train mile run; whilst, on the other hand, the cost of running is practically the same per train mile as in the case of the Metropolitan and District Companies—namely, sixpence. For 1893 we find the electric railway earned only about 2s. per train mile run, compared with 6s. in the case of the other companies; and as in all three cases the actual cost of running per train mile is 6d. this accounts for a good deal of the difference in ratio of working expenses referred to, and, of course, the ultimate effect is to nullify the advantage the electric railway possesses in the matter of capitalisation. The item of working expenses referred to is being reduced, however, considerably, and for 1893 it showed a reduction of £800 compared with 1892, though the train mileage run increased over that year by 38,400 miles. At the present time the ordinary stock, representing £630,000 out of the total capital of £862,000, receives a dividend of only 13s. 9d. per cent., so that a great deal of leeway has to be made up before the City and South London can be called a profitable venture for its shareholders. The next scheme for an electric railway was the Central London, which in 1891 received parliamentary sanction to construct a line from Shepherd's Bush to Cornhill. The next session of Parliament saw quite a host of applications for underground electric railways, including the Charing Cross, Euston, and Hampstead, Baker-street and Waterloo, Waterloo and City, Great Northern and City—all new schemes—and applications were also made by the two companies already incorporated for extensions of their systems. The City and South London sought powers to build a line connecting its present line south of the Thames with The Angel, at Islington; and the Central London applied for parliamentary sanction to the extension of its proposed line from the Bank to Bishopsgate All these schemes were submitted to a Joint Committee of the two Houses of Parliament, and, subject to modifications effected in the public interest, all the applications referred to received the sanction of Parliament in 1892 or 1893. Two of the companies referred to—the Waterloo and City, and the Charing Cross, Euston, and Hampstead—have since come before the public for the capital to carry out their schemes, and others will probably not be long in making their appearance.

* From the *Financial Times*.

There can be little doubt that the schemes which have up to the present time received the sanction of Parliament will, when completed, greatly facilitate travelling between many important points in the Metropolis, and do much to relieve the congestion of traffic in the main thoroughfares . . . It is also satisfactory to observe that the routes of the proposed lines are such as would appear to meet the public wants, and as far as the community in general is concerned they will be welcomed as valuable additions to means of communication in the Metropolis. Their prospects as profitable ventures for investors are more dubious, especially in view of the experience of the City and South London line. Nevertheless, the electric railway appears to offer a very good field for enterprise; for future inventions and improvements will no doubt do much to render it more profitable than it can be under existing circumstances. The following is a summary of the schemes for electric railways in the Metropolis which have received parliamentary sanction:

Company.	Capital authorised. Share capital.	Loans.
Charing Cross, Euston, and Hampstead	£1,416,000	£472,000
Waterloo and City	540,000	180,000
Central London	2,850,000	950,000
Great Northern and City	1,500,000	500,000
Baker-street and Waterloo	1,250.000	416,000
City and South London (Islington extension)	750,000	250,000

The first two schemes are those which have already come before the public. In the present session of Parliament the Central London is applying for an extension of the time within which its line is to be completed to the year 1900. The Baker-street and Waterloo is a scheme to connect the South-Western terminus more directly with the West-end, and is a companion scheme to the Waterloo and City, which has been received so favourably. Two of the South-Western directors are on the Board of the Baker-street and Waterloo Railway. It should be mentioned that the Islington extension of the City and South London is authorised as a separate undertaking, and includes powers to make a subway connecting it to the Brighton Station at London Bridge, and another connecting it with the Metropolitan and District Companies near the Monument. More will no doubt be heard of these various schemes before very long.

We have received from a well-informed correspondent the following notes on our recent editorial article, comparing the City and South London Electric Railway with the original underground lines:

"The very interesting and instructive remarks on electric railways, which appeared in your issue of the 9th, open up a very wide question which it would be impossible to exhaust in a volume, much less in a single column. Nearly everything you say will command general acquiescence among competent authorities, and the comparison raised between steam and electric railways is so far-reaching that it may be usefully carried a good deal farther than you have done. The promoters of electric traction may naturally object to the City and South London being selected as the test of their system, and you yourself acknowledge the drawbacks. They are, however, even greater than you have realised. A pioneer line, built under great difficulties, engineering and financial, it has not had, as yet, a fair trial in any sense. It was not even originally designed for an electric railway, but for a cable tramway. To show you how that affects the operations of the road, I need only mention three of the many drawbacks it entailed. The tunnels are smaller and more slightly built than if they had been designed from the outset for their present use—very much smaller than the tunnels on the new lines will be. Their diameter is only 10ft. 6in. against 11ft. 6in. and 12ft. 6in. on the new lines. The rolling-stock is lighter than it should have been, and deficient, not only in numbers, but in carrying capacity. The stations, too, are notoriously inadequate, especially the present terminus at King William-street, which is now being enlarged. The lifts, if they had to be rebuilt, would be made both larger and more powerful.

"But all these defects are trifling compared with the shortness of the platforms, which can only accommodate half trains of two or at most three carriages. In order to get full advantage of the busy hours of morning and evening, the trains ought to have had six or seven carriages. As they are, when traffic is heavy, they can only take a fourth of it, and during the long interval between the busy times they run half empty. Traffic would have been difficult enough for a new road to gather on such a route with two overhead railways, a tramway, and a score or more of omnibus lines running alongside, but the City and South London unfortunately handicapped itself in advance by this inelasticity of its carrying power. That it should, under the circumstances, earn as much as 2s. per train mile is gratifying in itself, and an earnest of better things to come. The authorised extension to Islington—which, by the way, will be a very superior line to the original—should bring a large increase of traffic, which, as you show, is all that the City and South London needs to realise the

Digitized by Google

full benefit of its economical system of working. Improved financial conditions will enable it to enlarge its stations, improve its equipment, and in other ways increase its earning power.

"Meanwhile, leaving earnings out of account, there is a very important lesson for railway investors in the comparison of working expenses per train mile, which you give one or two examples of. It is worth following into greater detail, as you will see from the subjoined tables, in which I have calculated the relative cost per train mile of the principal classes of expenditure on the two metropolitan roads and the City and South London:

TRAIN MILEAGE EXPENSES, METROPOLITAN AND SOUTH LONDON RAILWAYS, 1893.

Mileage, 1893.	Metropolitan.		City and South London.	
	—	Train miles, 2,126,841.	—	Train miles, 441,765.
	£	Per mile. Pence.	£	Per mile. Pence.
Maintenance of way—

December 13,479	26,951	5·368	1,087	0·590
	£185,446	36·833	£29,630	16·121

"It is not, of course, strictly fair to measure light trains of two or three carriages against heavy trains of eight or nine carriages; but this affects chiefly the locomotive power, as to which it may be observed that the present engines of the City and South London could haul double their actual loads. In the other items, maintenance of way, traffic expenses, general charges, and even rates and taxes, the advantage of the electric traction over steam is striking and indisputable. Maintenance of way, for instance, is on the City and South London little more than a ½d. per train mile, against close on 4d. per train mile on the Metropolitan, and 4¼d. on the District. The cause of this huge saving is now familiar to every railway engineer. The Greathead tunnel, once completed, is perfectly weatherproof. There is no smoke to corrode it, it needs no painting, and the rails, being fixed to the iron floor of the tube, require no ballasting and relaying. From a similar cause carriage repairs are very slight. Hardly ever exposed to the outside atmosphere, carriages remain clean and wholesome for a long time. Traffic expenses per train mile are low, for the evident reason that with a rapid shuttlecock service, working over a short length of road, many more train miles can be run per mile of road than on the Metropolitan, for instance, with its 52 miles of track to work over. Traffic expenses and general charges combined average, it will be seen, only 8d. per train mile on the City and South London, as compared with nearly 12½d. per train mile on the Metropolitan, and almost 14¾d. on the District.

"The aggregates are no less significant than the details. On the City and South London the whole cost of working, including rates and taxes, is about 16d. per train mile, while on the Metropolitan it exceeds 35d. per train mile, and on the District it almost reaches 37d. The City and South London might treble the weight and the carrying capacity of its trains without approaching the 9½d. per train mile of the District Railway, or the 10d. per train mile of the Metropolitan, while its other expenses would be little, if any, increased. Though by no means a flourishing specimen of an electric railway, it has already scored a strong point for electricity over steam."

TRIAL OF ELECTRIC PUMPING PLANT.

A trial was made in the works of Messrs. Ernest Scott and Mountain, The Close, Newcastle-on-Tyne, on Saturday last, of two sets of large electrically-driven pumps in course of construction for the Lothian Coal Company, Newbattle Collieries, Dalkeith, N.B. The trial was witnessed by a number of leading engineers of the district, as well as by others interested in collieries and electrical matters from a distance. The test proved very successful, and as this electrical plant is probably the largest pumping plant that has yet been put into a colliery electrically driven, it was of more than general interest. The general outline of the machinery is given in the annexed description, which has been forwarded to us by the company.

The installation consists generally of two horizontal engines, each capable of developing 150 effective horse-power with a steam pressure of 100lb. per square inch; two "Tyne" dynamos, each capable of giving an output of 60,000 watts at a speed of approximately 600 revolutions per minute; two electric motors, each of 60 h.p.; two sets of three-throw pumps, each capable of delivering 200 gallons of water per minute against a head of 650ft.; together with conducting cables, etc. Each engine is of the horizontal long-stroke type, fitted with Corliss valve gear in order to obtain the highest possible economy in steam consumption. The engines are fitted with cylinders 15½ diameter by 33 stroke; each engine is provided with an injection condenser worked by an extension of the piston-rod and placed behind the cylinders. By the adoption of the condenser a very considerable economy in steam consumption will be obtained. It is proposed to add two additional engines, making four in all, as soon as the present plant is started; three of the engines will be used for driving three dynamos, the fourth engine being used for driving the screens and other machinery in the colliery. The four engines will drive on to a main countershaft running the entire length of the engine-house; this shaft is fitted with four main driving pulleys for receiving the main driving belts from the engines and four dynamo pulleys for transmitting the power from the countershaft to the dynamos Each of the pulleys are fitted with clutches, so that they can be put in and out of gear as required, and by this arrangement any combination of engines and dynamos can be run as required.

At present two dynamos are being provided for working the two sets of electric pumps; provision, however, is made for four dynamos in all—the extra power will be used for driving additional pumps and haulage and other electrical machinery later on. The two dynamos are of Messrs. Scott and Mountain's improved mining type, each capable of giving an output of 60,000 watts—*i.e.*, 120 amperes at an E.M.F. of 500 volts when running at a speed of 600 revolutions per minute. The armatures are of Messrs. Scott and Mountain's improved type, admitting of perfect ventilation and ready repair in case of accident. The armature cores are positively driven from gunmetal drivers fitting into three keyways in the discs. The commutators are of extra length and diameter to ensure freedom from wear and tear, and are insulated with mica and mounted upon gunmetal sleeves, enabling them to be removed from the machines if required. Cast-iron sliding bed-plates are provided, enabling the slack of the belts to be taken up whilst the dynamos are running.

The main switchboard consists of an enamelled slate base fitted with two colliery switches with carbon sparking contacts, enabling the current to be switched off without any risk of burning the switch. A third switch is provided, so that either dynamo can supply current to either set of pumps. Two ampere-meters and two voltmeters are provided—*i.e.*, an ampere-meter and voltmeter to each dynamo—so that the E.M.F. and current can be measured as required.

The current from the dynamos to the pumps will be conveyed by four cables. The core of each cable consists of 19 wires 15 B.W.G. insulated with a thick coating of bituminised fibre. The cable is then very heavily armoured with galvanised iron wires, the inner armouring consisting of 29 wires No. 11 B.W.G, and the outer armouring consisting of 35 wires No. 11 B.W.G. The cables are made in eight lengths with joints in the centres; these joints are made in junction-boxes, so that they can be readily got at if required.

Digitized by Google

The pumps are of the vertical three-throw ram type, each set of pumps being capable of delivering 200 gallons of water per minute against a head of 650ft. when running at a speed of approximately 45 strokes per minute. The pump bodies for each set of pumps consist of three identical castings, interchangeable, and fitted with glands bushed with gunmetal. The suction and delivery valve-boxes are all independent, and fitted with an improved type of valve with double outlet. The connecting pipes are also interchangeable. This arrangement of pumps, valve-boxes, and connecting pipes enables the pumps to be run, assuming an accident should happen to any of the various parts. The rams are of gunmetal 7½in. diameter by 12in. stroke, fitted into cast-steel cross-heads working in slipper guides on the bed-plates. The connecting rods are of steel, fitted with bored and turned brasses at the crank-pin end and double eye with steel gudgeon at the cross-head end. The crankshafts are of the three-throw type, running in four bearings on the bed-plate. The shafts are 5in. diameter, the total length of bearing surface in the main bearings being 24in., and in the crank-pins 18in.

The power is transmitted from the countershaft, which runs in four bearings, to the pumps by means of two pairs of helical spur wheels and pinions, each pair of wheels being capable of transmitting the whole power if required. The motors drive the pumps also by two belts working on to two double-shrouded pulleys on the countershafts; each of the belts are capable of transmitting the whole of the power.

The electric motors are similar in construction and design to the dynamos, and are each capable of developing 60 effective horse-power when running at a speed of 600 revolutions per minute. Two main starting switches are being provided, and will be fixed in the pump-house, so that either set of pumps may be started as required, and the speed also regulated according to the duty which they have to perform.

COMPANIES' MEETINGS.

SOUTHAMPTON ELECTRIC LIGHT AND POWER COMPANY, LIMITED.

The annual meeting of the shareholders of the above Company was held at the offices, Southampton, Mr. G. T. Harper occupying the chair.

The **Chairman**, in moving the adoption of the report and accounts (which were given in our last issue), said he thought the shareholders all appreciated the efforts of those who had brought the Company to its present position, and their belief that it would be a progressive concern was perfectly justified. He thought that by making the Company almost a dividend-paying concern in two years they were justifying the anticipations of Mr. Miller, and he trusted the Company would be made a good dividend-paying concern. In order to assist in accomplishing this the directors had decided to forego their fees, amounting to £400. It was most gratifying that instead of having a great balance against them of £754. 19s. 9d., it had been reduced by this means, and by the profit of £170. 1s. 11d. on the last year's working, to £184. 17s. 10d. Next year they would show a much better result, because the sales of electric current for the first two months of the year already showed an increase of 50 per cent. over the corresponding period of last year. If that progress continued, and the working expenses were kept down, he believed that at the end of the year they should not only be able to pay the debenture debt, but a dividend on the ordinary shares as well. The directors hoped that the Company would so recommend itself to the general public that they would be able to provide the capital needed for the works without going to the bank for it. During the year much could be done with increased capital, and the directors looked to the shareholders for that capital. He read the following statement showing that the Southampton Company compared very favourably with many electric light companies:

Name of company.	Units debited to customers.	Works cost in pence per unit sold.	Total cost in pence per unit sold.
Southampton (L)...	53,848	3·36	4·32
Chelsea (L)	402,848	2·79	4·32
Notting Hill (L) ...	107,580	3·75	5·29
Preston (L)	149,636	4·17	6·98
Preston House-to-House (H)...	358,506	4·06	5·15
*Oxford (H).....	103,859	3·50	5·71
Leeds (H)	130 068	3·20	4·87

* Eight months only.

It should be noted that the output of the Southampton Company was very considerably lower than that of any of the other companies he had named, and therefore the costs might have been expected to come out higher in proportion. For comparison, he would give the figures of two companies for 1892 whose output more nearly approached theirs—viz.:

Notting Hill... . ..	75,667	5·86	8·93
National	79,650	4·28	5·90

(L) Low tension (as in Southampton).
(H) High tension (as in Bournemouth).

The above companies, whose expenses were higher in proportion than theirs, were the only companies whose accounts were already published. This statement was signed by Mr. J. H. Lee. In conclusion, the Chairman said that the report was made out by a practical man—their engineer—who prepared monthly tables of costs, so that the directors knew what the Company was doing. He thought it was very satisfactory that their cost of production was, with two exceptions, the lowest on the list.

Mr. F. B. Turner seconded the adoption of the report.

Mr. J. Miller, J.P., in supporting the motion, said that the balance-sheet was pleasing, for it showed that if the public had come forward and subscribed for shares instead of their having to pay interest on money borrowed from the bank, they would have been able to pay a dividend of 3 per cent. He asked whether anything had been done with regard to obtaining a provisional order? He thought it was a great thing, as they wanted to establish their right to supply the current to Southampton.

The **Chairman** said that nothing could be done till July, when notice would be given and steps taken to get a provisional order.

The motion was then put to the meeting and was adopted.

The retiring directors, Messrs. J. F. Obree and G. J. Tilling, were re-elected, and Mr. C. Cox was reappointed auditor.

BUSINESS NOTES.

Western and Brazilian Telegraph Company.—The receipts for the past week were £3,113.

Eastern Telegraph Company.—The directors have declared a quarterly interim dividend of 2s. 6d. per share.

Great Northern Telegraph Company.—The directors have declared a dividend of 8·3 per cent. for the year 1893.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 8th inst. amounted to £691.

Burton.—The electric light is to be installed at the new municipal offices at an expenditure not exceeding £997. 13s.

Burton.—The number of customers for the electric light is increasing. Orders for nearly 900 lamps have been received.

Blackpool.—The electric light is now provided almost continuously, the exceptions being between the hours of 8 a.m. and 1 p.m. on week days, and 8 a.m. and 4 p.m. on Sundays.

Monmouth.—Messrs. Bramwell and Harris have agreed to advise the Town Council on their drainage and electric lighting schemes for a fee of 100 guineas and out-of-pocket expenses.

County of London Company.—The letters of allotment of the first issue of 19,900 ordinary shares in the County of London and Brush Provincial Electric Lighting Company are being posted.

Anglo-American Telegraph Company.—Quarterly interim dividends of 9s. per cent. on the ordinary stock and of 18s. per cent. on the preferred stock have been declared by the directors.

Storage Batteries.—Since the issue of the prospectus of the International Electric Storage Company, the German patent has been granted to Mr. Theryc, and advice of same has been received this week.

West India and Panama Telegraph Company.—The directors recommend a dividend of 6d. per share on the first and second preference and 9d. per share on the ordinary shares for the half-year ended December 31.

Folkestone.—The Folkestone Corporation last week, after four hours' sitting and many previous meetings, approved of the scheme for the installation of electric light, at a cost of £35,000, by a majority of nine to five votes.

Bakewell.—A letter has been received by the Local Board from the secretary to the telephone company promising that the state of the wires, etc., in Bakewell, which were pronounced to be dangerous, should receive immediate attention.

Ship-Lighting.—Messrs. David Dunlop and Co., of Port Glasgow, have launched the ss. "Maria Herrera," built to the order of a Havana firm. She has been fitted throughout with the electric light by Messrs. Claud Hamilton, Limited.

Indo-European Telegraph Company.—After placing £15,000 to reserve, the directors recommend a balance dividend of 17s. 6d. per share, and a bonus of 20s. per share, making a total distribution of 10 per cent. for the year ended December 31 last.

Stock Exchange Quotation.—An application has been made to the Stock Exchange Committee to appoint a special settling day in the shares of the Oriental Telephone and Electric Company, Limited, in lieu of those of the old company of the same name.

Electric Jib Wharf Crane.—As will be seen from our advertisement columns, Messrs. C. H. Glover and Co., Hatcham Saw Mills, Ormside-street, Old Kent-road, S.E., invite tenders for a travelling jib landing crane, and for a dynamo and lighting installation.

Birkenhead.—The special sub-committee of the Finance Committed on electric lighting have resolved to purchase the plot of freehold land, containing about 3,152½ square yards, situated in Bentinck-street, for £1,576. Their action has been approved by the Finance Committee.

Portsmouth.—The Electric Lighting Committee of the Town Council have submitted certificates from Messrs. Waller and Manville for the payment of £2,850 to the contractor of the electric light works for machinery, conduits, electrical plant, etc. These have been passed by the Council.

Shirley.—At a meeting of the Shirley and Freemantle Local Board of Health, it was agreed to ascertain on what terms the old washing factory at Mousehole could be obtained. The Chairman, in answer to questions, stated that if they took these premises they would have the right to use the water power.

Digitized by Google

Weston-super-Mare.—The Electric Lighting Committee of the Town Commissioners reported on Wednesday that they had arranged for a canvass of the town to ascertain what public support was likely to be accorded to an electric lighting scheme.

City and South London Railway.—The receipts of the Company for the week ended April 8 were £852, against £842 for the same period last year, or an increase of £10. The total receipts for the first half-year of 1894 show an increase of £30 compared with those for the corresponding period of 1893.

Cheltenham.—The town clerk has laid before the Electric Lighting Committee of the Town Council the sanction of the Local Government Board to a loan of £1,600 for the purposes of electric lighting, repayable in 25 years, and to the use of part of the site of the destructor for the electric lighting station. The report has been adopted.

Bournemouth.—The Town Council have passed the following plans submitted by the electric supply company: fuse-boxes, Portarlington and Marlborough roads, extension of transformer pit in the Square and on Richmond-hill, the two latter being passed "subject to the covers being hinged to the satisfaction of the surveyor."

Buckingham.—At a meeting of the Town Council a tender has been received from the gas company for lighting the public lamps. It was stated that the Council having accepted the tender of Messrs. Parr and Gillies to light 10 of the public lamps with the electric light, they could not accept the tender of the gas company to light those lamps.

Scarborough.—The Scarborough Bridge Cliff Company have decided to introduce the electric light into the theatre. The cost of the installation is estimated at £300. The current will be obtained from the local supply company. The introduction of the light into other buildings and grounds of the company has been left for future consideration.

Tenders for Emsworth (Hants).—Tenders are invited by 26th inst. for the lighting of the public lamps for one year, commencing July 22, 1894, to July 21, 1895, for the Inspectors of Lighting. Tenders will be considered at the meeting of the inspectors to be held on May 7, and should be delivered to Mr. J. W. Loader Cooper, clerk, Queen-street, Emsworth.

Wisbech.—The Town Council have ordered that tenders for public lighting shall be advertised for. At a meeting of the Council Mr. Stanley asked if it was the intention of the Council to advertise for electric lighting, and on his proposition it was decided that the advertisements should read, "lighting by gas, electricity, or otherwise, for one, two, or three years."

Tenders for Brighton.—The Town Council, as notified in our advertisement columns, are asking for tenders for the supply and erection of Willans engines, continuous-current dynamos, pipe work, spare armatures, etc. Specifications can be had on application at the town clerk's office at the Town Hall, Brighton. Sealed tenders to be sent in by the 30th inst.

Tenders for Telephone.—As stated in our last issue, the Committee of Visitors of the North Wales Counties Lunatic Asylum invite tenders for the construction and maintenance for a period of five years of a telephone between the asylum and Glanywern Hall, a distance of about three miles. Further particulars may be obtained from Mr. Wm. Barker, clerk to the Visitors, the Asylum, Denbigh.

Keighley.—Colonel Hasted, R.E., of the Local Government Board, has held an enquiry into an application of the Town Council to borrow £41,000 for gasworks purposes. The Town Clerk stated that in view of the determination of the Corporation to apply in the coming session for powers to supply the electric light, the profits in the future could not be expected to be as large as formerly.

New Firm.—We are informed that Mr. Cathcart, late partner in the firm of Messrs. Cathcart, Peto, and Radford, has commenced business under the title of Messrs. C. H. Cathcart and Co., and has opened offices and works at 4, Dorset-buildings, Salisbury-square, Fleet-street, E.C., to which address all business communications should in future be sent. The telegraphic address is "Coefficient, London."

Aberdeen.—The Road Sub-Committee of the Aberdeen District Road Committee have reported that the Northern Electric Supply Company had asked to be allowed to lay mains across the Deeside-road at Cults at two points, that the sub-committee had resolved to recommend that the application be agreed to under certain conditions, and that the rent be £1 per annum. The committee have adopted the recommendation.

Lighting of Derby House.—Messrs. Drake and Gorham have been entrusted with the lighting of Derby House, where extensive alterations and additions are being made. The few lights which already exist in one or two rooms will be taken away entirely, and the arrangement throughout will be in accordance with their usual system in work of this class—viz., shaded lighting. The number of lights being installed is about 400.

Taunton.—The Town Council have presented Mr. J. A. Robinson with a silver-plated liqueur stand, in recognition of the valuable assistance and advice he had rendered them in connection with the electric light works. Mr. Robinson has for some years been locomotive superindent of the Great Western Railway at Taunton, and he has recently been promoted to a higher position in the locomotive department, which has necessitated his removal to Newton Abbot.

New Installations.—Messrs. Rashleigh Phipps and Co., of 102, Oxford-street, have just received instructions for the electric lighting of Mr. George Grossmith's house in Dorset-square, which has to be completed within a fortnight, to be ready for his return from America. This firm is also engaged upon the electric lighting of the Earl of Fingall's house in South Audley-street, as well as a complete plant at Mr. Netlam Rattray's mansion at Bear Hill, Twyford.

Portobello.—At a meeting a few days ago of the Town Council, the report by the special committee appointed in November to enquire into the question of public lighting was submitted. The report said that the second part of the remit made to the committee was to enquire into all the available sources of lighting supply, and in this direction the committee enquired as to the advisability of introducing electricity, but found that at present it would be too expensive a system to recommend.

Radcliffe.—The Electric Lighting Committee of the Radcliffe Local Board have recommended the approval of the high-pressure alternating system for the lighting of the district. At a meeting of the Board, the Chairman said that in all probability at the next meeting there would be a resolution submitted on the basis of the two reports by the experts who had been engaged. The committee would also be prepared to suggest that the Board apply for an order for powers to carry out a scheme of electric lighting.

Exhibition of Electric Heating and Cooking Apparatus.—An exhibition of electric heating and cooking apparatus is now being made by Messrs. Crompton and Co. at the showroom of the London Electric Supply Corporation, Belgrave-mansions, Ebury-street, S.W. The first demonstration was given yesterday (Thursday), between 3.30 and 5 p.m., and further displays will be given every Thursday until further notice. Apart from this, the apparatus is always on view between 11.30 a.m. and 7 p.m.

International Electric Storage, Limited.—This Company has been registered with a capital of £200,000 in £5 shares. The object is to acquire all or any part of the shares, works, property, and liabilities of the Universal Electric Lighting Company, Limited; to acquire all or any of the letters patent of Messrs. Theryc and Oblasser for electric accumulators granted to them in the United Kingdom and elsewhere, and to generate and distribute electricity. The first signatories are: S. F. Page, J. L. Higgs, J. G. B. Elliott, J. H. Mace, B. H. Van Tromp, Colonel E. Villiers, and A Schanschieff.

South Staffordshire Tramways Company.—On Wednesday, the petition presented by shareholders for the winding up of this Company again come before the Courts. Objection was taken that a company which had been incorporated by Act of Parliament could not be wound up on a petition presented by a shareholder. After some argument, Mr. Justice Vaughan Williams overruled the objection, and said he thought there might be some benefit to the shareholders in winding up, because he thought there would be a surplus to be divided. The persons who charged fraud, however, must furnish further evidence. The petition was accordingly adjourned for further evidence.

Tenders for Working the Leeds Tramways.—The Corporation having become owners of the tramways, invite tenders, at a rental per mile single line of track, for the working of the lines, for the alternative periods of seven, fourteen, or twenty-one years. There are about 27¾ miles of tramways calculated as single track. Those tendering must state what motive power they propose using—that is to say, whether horse, steam, cable, electric, or what other power—and whether over specified parts or the whole of the system. Forms of tender and conditions of letting may be obtained on application to the town clerk. Tenders must be addressed to the chairman of the Highways Committee, Town Hall, Leeds, by May 5.

Bootle.—At a meeting of the Town Council held on Wednesday, Mr. Morton moved the confirmation of the proceedings of a sub-committee as to electric lighting which recommended that the system of lighting by electricity all the Corporation buildings, including the Town Hall and offices, library and museum, police court and station, and baths, be adopted. The sub-committee also recommended that tenders for the execution of the necessary work be obtained and submitted to the next meeting of the Council, and that the Finance Committee be directed to apply for the sanction of the Local Government Board to a loan not exceeding £3,600 with which to carry out the works. The motion was adopted.

Great Missenden (Bucks.).—An exhibition of electrical cooking and heating arranged by Messrs. Habgood and Smith, electrical engineers, 49, Queen Victoria-street, E.C., and Great Missenden, was held at this village on 4th and 5th inst. The apparatus, which comprised ovens, frying-pans, kettle, flatirons, etc., was lent by Messrs. Crompton and Co., Limited. Mr. Habgood gave a short introductory lecture on the application of electricity to heating purposes. During each evening, samples of the electric cooking were given to everyone present. Music was rendered at intervals, and altogether very pleasant evenings were spent The lighting of the village is still progressing favourably, and is being well taken up by private consumers.

Watford.—Mr. Rogers has written to the Local Board in reference to electric lighting, stating that it was now nearly 18 months since there was formed in Watford an electric lighting company with the Earl of Essex as president. On receiving a communication from the Board, the company decided not to proceed further with the scheme, as it was understood the Board would themselves apply for a provisional order. He asked whether it was still the intention of the Board to do so. At a meeting of the Board the Chairman said he thought it was still the Board's intention to keep the matter in their own hands; but it was suggested by Mr. Andrews that the condition of the Board's finances did not at present justify the carrying out of a scheme.

Digitized by Google

Hotel-Lighting.—On Thursday last week, Mr. Edwin Stephens, proprietor of the New Drayton Court Hotel, Ealing Dean, held a reception to celebrate the opening of that hotel. The electric lighting was universally pronounced as being perfect. The plant consists of one of Mr. Ronald Scott's new type of compound-wound dynamos, driven by a high-speed Crossley gas-engine, no accumulators being used. The dynamo is provided with a heavy flywheel, and Mr. Ronald Scott was congratulated on all sides on the perfect steadiness of the lights. It was shown that, whether the plant was doing one-tenth or full load, the perfect steadiness was maintained throughout. The number of lamps in use is about 100.

Dublin.—The National Telephone last year absorbed the Irish Company, and complaints have since been made in Dublin as to the company's attitude to subscribers there. Concessions have, however, now been made. In the important question of the rental, the £12 rate for exchange wires has been reduced as from January 1 last to £10, and the condition as to the five years' term withdrawn, and subscribers are allowed to remain on on the previously existing contracts. As to the future management of the Dublin concern it practically remains unchanged, as the Board of the Irish Company has been continued as a local Board for the purpose of advising the Board of the National Company.

Chadwick v. Woking Electric Company.—A motion for judgment in the debenture-holder's action, Chadwick *v.* the Woking Electric Supply Company, Limited, was made last week before Mr. Justice Stirling. The company had issued 60 debentures of £50 each and six of £500 each, and there had been default in payment of the interest. The principal thereupon became due and payable. Counsel explained that the receiver appointed in the action had entered into a provisional contract with certain persons for the sale of the whole business as a going concern. Under these circumstances his Lordship made an order for the usual account of the amounts due on the debentures, and an enquiry as to priority, with liberty to apply in chambers as to the realisation of the property.

Dover.—At a meeting of the Dover Town Council last week, a further letter was read from the Board of Trade with reference to the electric lighting regulations. The surveyor reported that he had agreed to allow the electric light company to put down their mains, and it had been thought advisable to put them under the footways instead of the roads, so that when connections were made with houses the paths need not be all broken up. The men in the employ of the Council were digging the trenches and repairing the paths in accordance with the agreements with the company, the latter to pay for the labour, etc. The positions of the electric light lamps were also reported upon. The town clerk announced that the £200 deposit by the electric light company to cover the cost of the works had been paid.

The Alhambra Theatre.—The Theatre and Music Halls Committee of the London County Council report that they have received a plan, submitted by Mr. P. W. D'Alton, engineer to the London Electric Supply Corporation, Limited, showing the formation of a converter-chamber in the basement of the Alhambra Palace for the purpose of enclosing transformers supplying electric light to the stage. They recommend that the plan be approved on the conditions that the walls of the chamber be not less than 9in. thick; that a self-closing wrought-iron door, fitted in a wrought-iron frame with a 3in. lap, built into the wall, be provided to the chamber in lieu of the present one, which is too slight; and that the ventilation and lighting of the room be carried out to the satisfaction of the engineer of the Council.

Notices Under Electric Lighting Acts.—The Highways Committee of the London County Council have considered four notices from the House-to-House Electric Light Supply Company of intention to lay mains on the west side of Gilston-road, on the north side of Lexham-gardens, along one side and across Wright's-lane and in Cheniston-gardens, and in a part of Gloucester-road. Both high and low tension mains are proposed to be used. The committee recommended that the sanction of the Council be given to the works referred to in these notices. They have also considered a notice from the Charing Cross and Strand Electricity Supply Corporation of intention to lay mains across and along a part of the east side of Adelaide-street. The committee recommended that sanction be given to the works.

Indo-European Telegraph Company.—The directors state that the revenue from all sources for 1893 amounted to £122,860, as compared with £117,479 for 1892, an increase of £5,381. The expenses were £64,960, as against £62,149, an increase of £2,811. Deducting these expenses, taking credit for £7,558 brought over, and debiting income tax, there remains a sum of £63,952. From this £15,000 has been placed to reserve, and that sum, together with £10,625 amount of interim dividend, have to be deducted, leaving a balance of £38,327. The directors now propose to declare a dividend for the last six months of 17s. 6d. per share, making, with the dividend already paid, 6 per cent., and a bonus of 20s. per share, both free of income tax—in all, 10 per cent. for the year, carrying forward £6,452 to the credit of 1894.

Ayr.—The burgh surveyor, Mr. John Eaglesham, has presented a report and plan to the Town Council as to the proposed installation of the electric light in the burgh. He estimated the total number of lights at 4,000 for private consumption, with 15 2,000-c.p. street lights to replace 95 gas lamps. It was estimated that, as compared with gas, the price of which in Ayr is 4s. 2d. per 1,000ft., the expenditure for a year's burning of about 500 hours would be, for eight-candle lights, gas 6s. 3d., electric light 6s. 10d.; for 16-candle lights, gas 8s. 4d., electric light 12s. 10d. The estimated cost of laying down steam plant for such an installation would be £11,000. The annual outlay, including capital outlay, was estimated at £1,641, and the income for 3,000 lights, in addition to street lights, £1,650. It was agreed to ask Mr. Robert Hammond to visit and survey the burgh with a view to the introduction of the electric light.

Presentation at Brighton.—A complimentary dinner to Mr. G. J. Philpott, chief engineer of the Brighton and Hove Electric Light Company, was held at the Imperial Hotel on Saturday evening. After the loyal toasts the chairman (Mr. G. Spencer Hawes), in presenting to Mr. Philpott a handsome gold watch and chain, referred to the long time that Mr. Philpott had been connected with the company and to the respect in which he was held. The chairman then formally presented the watch to Mr. Philpott, adding that it was accompanied by a feeling of goodwill as sterling in its standard of sincerity and heartiness as the metal of which the souvenir was composed. Mr. Philpott, in responding, said that he was quite unable to thank them sufficiently for the honour that had been done him, but he could assure them that that splendid present would always be an interesting memento of his connection with the Brighton and Hove Company.

The Bury (Lancs.) Tenders.—The tender of Mr. S. H. Heywood, of Manchester, has been accepted for the supply of electric light fittings, including switchboards, lamps, wiring, etc., for lighting the technical school now in course of construction in Broad-street, for the Technical School Committee of the Corporation. The following also tendered: Dugdill and Co., Failsworth; Moorhouse and Son, Burnley; E. Dewhurst, Preston; Northern Counties Company, Manchester; J. H. Hindle, Bury; Doninson, Parmiter, and Co., Manchester; Corlett Engineering Company, Wigan; Barnett and Co., Newcastle; Laing, Wharton, and Co., London; Manchester Edison Company, Manchester; Bury and Pope, Burnley; J. Faulkner, Manchester; T. Barton, Blackburn; Drake and Gorham, Manchester; Lowcock, Hill, and Co., Manchester; Graham and Biddle, London; Strode and Co., London; Andrews and Co, London; H. A. Clegg and Co., Manchester.

Lighting of Omnibuses and Tramcars.—As mentioned in previous issues, for some five weeks past a car has been run by the London Street Tramways Company from Westminster Bridge to Streatham which has been fitted by Mr. Froggatt with two 5-c p. lamps inside and two lamps of the same power outside. Inside the car it is possible to read the smallest print with comfort. Outside two lamps are placed, one at each end of the car, and it is also possible to read small print when seated in the middle of the car. The lamps are raised on iron supports, and are visible at a distance. It is proposed to have a different coloured lens for each lamp, so that a passenger can tell at a glance the destination of the car. The current is supplied by batteries carried under the seat of the car. The system has given satisfaction to the company, and it is said that they are about to fit the whole of their cars with it. It has also been adopted by the Atlas and Waterloo Omnibus Association and by the Star Omnibus Company.

Eastern Extension Telegraph Company.—The report of the Eastern Extension, Australasia, and China Telegraph Company for the half-year ended December 31 states that the gross receipts, including Government subsidies, amounted to £251,698, against £247,767 for the corresponding period of 1892. The working and other expenses absorbed £76,575, against £91,769, leaving a balance of £175,123. From this is deducted £4,015 for income tax, and £31,895 for interest on debentures, debenture stock, and contribution to sinking fund, leaving as the net profit £139,213, which, with £81,117 brought forward from the previous six months, shows an available balance of £220,330. One quarterly interim dividend of 1¼ per cent. has been paid for the half-year, and it is now proposed to distribute another of like amount, making, with the interim dividends paid for the first six months, a total dividend of 5 per cent. It is also proposed to pay a bonus of 4s. per share, or 2 per cent., making a total distribution of 7 per cent. for the year. The balance of £107,830 has been carried to the general reserve fund, which, after being credited with interest received on investments, now stands at £633,686.

Isle of Man Tramways and Electric Power.—The Isle of Man Tramways and Electric Power Company, Limited, has been formed with a nominal capital of £150,000 for the purpose of purchasing and working under one management the Isle of Man Tramways and the Douglas Bay Estate, formerly the Howstrake, Tramway, with the authorised extensions either prospective or in course of construction. The whole of the undertakings—permanent way, land, buildings, and other property—is to be handed over as a going concern fully equipped and in working order for £175,000, the vendors reserving the right to subscribe for one-third of the capital. The prospectus states that the Isle of Man Tramways is one of the best paying in the kingdom, the net profits in 1891 being £2,820, in 1892 £2,907, and in 1893 £3,784. An annual gross revenue of £28,250 is estimated, of which, after allowing for working expenses and the interest on debentures and preference shares, £9,025 is expected to be available for dividend on ordinary shares and the formation of reserve. There are now offered for subscription 125 000 £1 shares, of which £50,000 are 6 per cent. preference and 75,000 ordinary; £50,000 debentures in bonds of £20, or multiples of £20, are also to be issued. The list closes on or before to-morrow (Saturday).

Bedford.—In our last issue reference was made to the deputations who had waited upon the Board of Trade with regard to the question as to who should supply the electric light in the town, and to the decision of the Board of Trade in the matter. It will be remembered that it was left to the Corporation to decide whether they would or would not carry out their electric lighting powers. At a meeting of the Corporation on Monday, the question was discussed at considerable length. The Mayor moved that the

Digitized by Google

authority carry out the supply in the compulsory area set out in proposed provisional order of the Bedford Electric Light Company, Limited, before January 1, 1895. The motion was seconded, but an amendment was proposed by Mr. Blaydes that the authority before committing the town to any further expenditure in connection with the installation of the electric light order a poll to be taken to ascertain whether they wish the authority or a company to undertake the electric lighting of the town. This was seconded, and after further discussion, the Mayor put the amendment, which received 11 votes as against 13; it was therefore lost. On the substantive motion being put, it was carried by 14 votes to 11. A motion was then carried empowering the Electric Lighting Committee to carry into effect the foregoing motion, including the employment of an engineer.

Bristol.—In our last issue we mentioned that the Bristol Sanitary Committee were to have before them at a meeting their half-yearly estimates, including that for electric lighting. The estimate for the half year, March to September, amounted to £4,750, as compared with £2,663 in the corresponding half-year of 1893. Mr. George Pearson, the vice-chairman of the committee, pointed out, in connection with the accounts, that the saving in gas for the year would be about £1,700. The Electric Light Committee, however, had to spend much more than that to give the city the light it was receiving. Their estimate was that it would cost £2,400 for the electric light they had now in the streets, and for which they formerly paid in respect of gas about £1,700. That enabled the Electric Lighting Committee to reduce their claim by about £800, the amount of the estimated value of the electric light for the coming half-year, and by the repayment of £1,600, an instalment of the loan, which they should make during the coming half-year. That meant that £2,400 of the £4,750 asked for under the head of electric light would not be lost to the city, so that the actual cost of the electric light for the half-year was £2,350. Opposition to the electric tramway to Kingswood still continues. The Chairman of St. George's Local Board has informed the Board that he has interviewed several residents at West-street, who objected to the proposed electric tramway to Kingswood on the ground that portions of that thoroughfare were not wide enough to allow of the extra traffic which the scheme, if carried out, would entail. Although he had not been able to convince these persons of the unsoundness of their arguments, he felt that their opposition would not upset the scheme, though some little delay might be caused.

Lighting at Accrington.—The minutes of the Legal and Parliamentary Committee, presented at a meeting of the Town Council last week, contained a recommendation to the Council to put down an installation of electric light to supply not less than 2,000 16-c.p. incandescent lamps, with provision for extension. On the minutes coming up for confirmation, Mr. Duckworth asked if nothing more could be done to influence tradesmen in regard to adopting the electric light. Mr. William Robinson moved an amendment that the minutes be referred back. He objected to the light from a financial point of view. If they were bound to adopt the light in order to keep out private companies, he thought they might adopt some cheaper scheme. Mr. Grace seconded the amendment. Seeing that electric light was likely to cost something like £10,000, he was not in favour of proceeding with it. They had had a deputation at Morecambe, but he had not heard that they were making 1 per cent. at Morecambe, and he would not go in for a business that was not paying. If they could have produced electricity as cheap as they talked of, they would not have gone in for the gasworks. He did not see the sense of opposing themselves by spending money they knew they could not have interest on. Mr. Eli Higham, while of opinion that the light would not pay for the first two or three years, thought it would eventually. There were many enterprising electricians who would be willing to come into the town and light it. They had got the necessary parliamentary powers, but the time had gone, and unless they were willing to take some steps they could not both hold their hands themselves and prevent other people from coming in. They were not in favour of another monopoly being formed. He was of opinion that when the shopkeepers saw the light they would quickly adopt it; that had been the case in Burnley. He only asked either that the Council should decide to go on with it or decide that some other party should come in. The minutes were eventually referred back to the committee.

PROVISIONAL PATENTS, 1894.

APRIL 2.

6512. **Improvements in dynamo-electric generators and motors and allied machines.** Frederick Henry Royce, 53, Arcade-chambers, St. Mary's-gate, Manchester.

6528. **Improvements in dynamo-electric generators and motors and allied machines.** Frederick Henry Royce, 53, Arcade-chambers, St. Mary's-gate, Manchester.

6554. **Improvements in or additions to metallic tubular telegraph poles and metallic tubular poles for other purposes.** Bullers, Limited, and Edward John Chambers, 7, Staple-inn, London.

APRIL 3.

6606. **Systems for controlling electric lights.** Charles Arthur Allison, 52, Chancery-lane, London. (The Electrical Speciality Company, United States.) (Complete specification.)

6623. **Improvements in electric lighting apparatus.** Percy Ruskin Allen, 46, Lincoln's-inn-fields, London.

6649. **A new or improved mechanical indicator for electric and other bells.** Abraham Kershaw, 33, Chancery-lane, London.

6661. **Improvements in electric switches.** Thomas Joseph Rorke, 45, Southampton-buildings, Chancery-lane, London.

APRIL 4.

6721. **Improvements in apparatus for signalling between police stations and district call-boxes.** The National Telephone Company, Limited, and Charles Eggar, 62, St. Vincent-street, Glasgow.

6732. **Improvements in apparatus or machinery for making draught extinguisher strips for covering electric cable wires with ribbon and for like uses.** George Clapham, 6, Lord-street, Liverpool.

6742. **An electrically-operated electric switch.** Siemens Bros. and Co., Limited, and George Sylvester Grimston, 28, Southampton-buildings, Chancery-lane, London. (Complete specification.)

APRIL 5.

6776. **Improvements in continuous recording instruments.** Herbert Nalder, Charles William Scott Crawley, and Alfred Soames, 16, Red Lion-street, Clerkenwell, London.

APRIL 6.

6850. **Electric lamp protector.** William Thomas Ungley, jun., 117, St. John-street-road, Clerkenwell, London.

6888. **Improvements in telegraphic and telephonic apparatus.** John Imray, 28, Southampton-buildings, Chancery-lane, London. (La Société Anonyme pour la Transmission de la Force par L'Electricité, France.)

6912. **Improvements in and relating to moulds for casting grids for the active material of electrical accumulators.** The firm of Kölner Accumulatoren-Werke Gottfried Hagen and Carl Beyer, 45, Southampton-buildings, Chancery-lane, London.

6917. **Improvements in apparatus for electrolytical purposes.** Herbert Guthrie, 46, Lincoln's-inn-fields, London.

APRIL 7.

6942. **Improvements in "cords" and plugs for telephonic switchboard circuits.** Daniel Sinclair, 62, St. Vincent-street, Glasgow.

6947. **Improvements in plates or electrodes for accumulators.** Robert J. Gülcher, 6, Lord-street, Liverpool. (Complete specification.)

6975. **Improvements relating to the manufacture of plates or electrodes for electric accumulators or secondary batteries, and to machinery or apparatus therefor.** Arthur James Smith and Henry John Wright, 11, Southampton-buildings, Chancery-lane, London.

SPECIFICATIONS PUBLISHED.

1884.

10215. **Electrical tramcars, etc.** Reckenzaun. (Second edition.)

1892.

13894. **Submarine telegraph cables.** Preece. (Second edition.)

23101. **Galvanic batteries.** C. A. J. H. and H. E. R. Shroeder.

1893.

6205. **Distributing electricity for lighting, etc.** Wood.

9380. **Breaking electric circuit.** Haddan. (Reisinger.)

9557. **Dynamo-electric machines.** Prentice.

10942 **Primary voltaic batteries.** Walker and Wilkins.

24517. **Advertising reflector for electric light globes.** Mockler.

24911. **Electric cables.** Dewees.

1894.

3020. **Induction electrical machines.** Tudsbury.

3384. **Electric lamps.** Turnbull.

NOTES.

Nantes.—An extension of the public arc lighting is to be made by the Municipality.

Saint-Leonard.—This district in the Haute-Vienne is to be lighted electrically on July 14.

Marseilles.—The Municipality have approved of the extension of the electric light in the town.

Hastings.—The Palace Hotel is now being lighted by electricity, and it will reopen to-morrow (Saturday).

Saint-Clers.—M. Albert Lafforgue is about to establish a central electric and power station at Saint-Clers, Gers.

Chlorate of Potassium in France.—Works for the electrolytic production of chlorate of potassium are being erected in Savoy.

Salon.—The Municipality of Salon, Bouches-du-Rhône, have given the concession for the electric lighting of the town to M. Grammont.

Madras.—The severe heat which has prevailed has retarded the work of constructing the permanent way of the Madras electric tramway.

Lecture.—Mr. T. Scott Anderson gave his second lecture on electrical engineering at the Central Higher School, Sheffield, on Monday.

Buckingham.—The Town Council have asked the electric light company to tender for the remaining public lighting with incandescent or arc lamps.

Bombay.—Messrs. J. Fleming and Co., of Bombay, are putting up an electric light installation in the Arthur Crawford Markets for the Bombay Municipality.

Budapest.—The Hungarian Ministry of Commerce has approved of the bulk of the project for the establishment of an electric railway on the quays of Budapest.

Institution of Mechanical Engineers.—The anniversary dinner was held on Wednesday evening at the Freemasons' Tavern, Prof. A. B. W. Kennedy presiding.

Society of Arts.—On Wednesday next, at 8 p.m., a paper on "Some Recent Developments of Photographic Chemistry," by Mr. Chapman Jones, F.C.S., will be read.

Charing Cross-Hampstead Railway.—The South-Eastern Railway Company have withdrawn their petition against the Charing Cross, Euston, and Hampstead Railway Bill.

Strassburg.—Tenders are to be invited by the municipality for a central electric light station for this city. The plans of Herr Oscar von Miller will have to be followed.

Manchester.—The members of the Gas Committee of the Corporation met last week at the electric light station to witness the unveiling of a tablet recording the starting of the works.

That New Reservoir. — "Is not a dynamo a reservoir?" asked a reporter the other day. "Yes," was the reply; "it's a kind of boiling tank to keep the electricity hot."

The Guildhall.—The Court of Common Council decided last week to extend the electric light installation at the Guildhall to the art gallery at an estimated cost of £290, inclusive of fittings.

Coatbridge Electricity Works.—We have received a copy of a pamphlet describing these works and the opening ceremony on the 31st ult. The works were described in our issue of the 6th inst.

Electricity in the Navy.—It is reported that electricity is to be increasingly utilised as a motive power in the British Navy, and that every gun on future warships will be equipped with electrical appliances.

The Institution.—A paper on "The Cost of Electrical Energy," by Mr. R. E. B. Crompton, M.I.C.E., vice-president, will be read at a meeting of the Institution of Electrical Engineers on Thursday next, the 26th inst.

Orleansville. — M. Gastambide, who has been the successful tenderer for the lighting of this town, is busily engaged in the installation of the station. The generating plant will comprise two 50-kilowatt Patin alternators.

Proposed New French Cable.—The Minister of the Colonies is about to bring in a Bill authorising the laying of a supplementary cable between Obock and Djiboutil, two French colonial stations on the Red Sea.

Electric Haulage Plant.—Some discussion took place last week at a meeting of the Mining Institute of Scotland, on a paper read at a previous meeting by Mr. Forgie on "Electric Haulage Plant at Drumbreck Colliery."

Budget Item.—We pay taxes for various things, but not for wind. The directors of the Rollason Motor Company hope that the Chancellor of the Exchequer will not impose a tax on their using wind for driving the Rollason motors.

Plymouth.—The Town Council will oppose the local gas company's Bill now before Parliament, in which powers are asked to supply the electric light, as the Council are obtaining a provisional order for the same purpose.

Serajewo.—The municipal authorities have decided to introduce the electric light, and also to build an electric tramway. They have arranged with the Hungarian Mortgage Bank, of Budapest, for a loan of the money necessary.

Provisional Orders.—Permission has been given to bring a Bill in the House of Commons to confirm certain provisional orders made by the Board of Trade under the Electric Lighting Acts, 1882 and 1888, relating to Chesterfield and Buxton.

Brechin.—The Municipality have decided, in connection with a motion to apply to the Board of Trade for a provisional order to supply electricity, to postpone the matter for a month, for the purpose of obtaining further information on the matter.

Sheffield.—A meeting of the directors of the Sheffield Electric Light and Power Company was held on Wednesday, when the applications for the new shares were considered and allotments made. The capital required has been fully subscribed.

King's College, London.—The thirty-fourth annual dinner of the old students will take place at the Holborn Restaurant on Wednesday, May 30. Further information may be obtained from Mr. Wm. Vincent, honorary secretary of the committee.

The Joule Fund.—The sum of £258, representing the amount handed to the Manchester Literary and Philosophical Society as the surplus of the Joule Memorial Fund, has been invested as a nucleus of a Joule Fund to be administered by the society.

North of England Institute of Mechanical Engineers.—A meeting of the members of this institute was held at Newcastle on Saturday afternoon, when Prof. H. Stroud, M.A., D.Sc., read a paper on "Magnetic Delineation and its Variations."

Electric Lighting of Derry.—The Local Government Board has agreed to grant to the Derry Corporation a

Digitized by Google

further loan of £2,870 in excess of the original loan, so as to enable the Corporation to complete the original scheme for the erection of 160 arc lamps.

Cardiff.—The Lighting and Electrical Committee of the Cardiff Town Council on Tuesday decided to carry out the recommendation of the Watch Committee, and fix distinctive lights upon certain lamps in the town, which will indicate the position of the fire-alarm boxes.

Crecy.—A thirty years' concession has been granted to M. O. Patin for the electric lighting of Crecy-en-Brie, Seine-et-Marne. A hydraulic motor will drive a 25-kilowatt Patin alternator, giving current at 2,000 volts, which will be reduced by transformers at the places where it is used.

Carbon Plates and Batteries.—The Atlas Carbon Manufacturing Company, Limited, of Ewer-street, Southwark-street, S.E., have sent us a copy of their price-list of carbon plates and rods, and of Leclanché and other batteries. The company supply carbons and batteries of all kinds.

Personal.—We understand that Mr. R. W. Weekes has signed an agreement with Messrs. Johnson and Phillips as head designer. Dr. Tilden, F.R.S., Professor of Chemistry at Mason College, has been appointed Professor of Chemistry at the Royal College of Science, South Kensington.

A Progressive Supply Company.—The number of 8-c.p. lamps supplied by the Metropolitan Electric Supply Company increased from 124,000 in 1892, to 166,000 in 1893. The present number of lamps connected is 175,000, and further applications continue to be received in satisfactory numbers.

Electricity in Agricultural Operations.—The United States Senate Committee on Agriculture has made a favourable report upon a Bill to establish an experimental electrical station for the purpose of determining whether electricity can be profitably applied as a motive power in the propulsion of farm machinery.

Caen.—The Chamber of Commerce has decided to light the port and water approaches by means of the electric light, by which navigation can be carried on at any hour. The report, containing all the particulars necessary for carrying out the project, will be placed at the disposal of firms desirous of tendering for this important affair.

Prof. Forbes Forgot This.—Two men—impressed with the mighty avalanche of waters—were gazing upon the Falls of Niagara. Says one: "Ah! there's a tremendous waste of water!" The other replied: "So you feel practically interested in it; are you an electrical engineer?" "Oh, no! only a dairy farmer," was the answer.

Long-Distance Telephony.—We recently referred to the opening of telephonic communication between Canterbury and London. Conversation has since then been carried on between the district office at Canterbury and persons at Newcastle-on-Tyne, Manchester, Birmingham, and elsewhere. These lines are not, however, yet open for public use.

Electric Lighting Provisional Orders.—The Board of Trade have made orders under the Electric Lighting Acts relating to Barrow-in-Furness, Buxton, Chipping Wycombe, Chesterfield, St. Helens, West Hartlepool, Grimsby, Harrow, Leyton, Monmouth, Peterborough, and St. Austell, and Bills to confirm them have been just laid before the House of Commons.

Municipalisation of Tramways.—It is stated that the London Street Tramways Company will carry to the House of Lords the appeal against the decision of the arbitrator in the case at issue between them and the London County Council, as to the acquisition by the County Council of certain of the company's lines, which was upheld on Thursday of last week in the Court of Appeal.

Standard Screw Threads.—The German Union of Electricians at their first general meeting, held at Cologne last year, appointed a committee, under the chairmanship of Prof. Hagen, for the introduction of a standard screw thread. The committee have just held a sitting, and the result of their labours will be presented at the general meeting of the union to be held in Leipzig in the middle of June.

Thomas Parker, Limited.—Mr. T. Parker, we understand, has not severed his connection with electrical work, but has become the head of another manufacturing company, the title of which is "Thomas Parker, Limited." The capital for this Company has, we hear, been all privately subscribed, so that no prospectus will be issued to the public. The works of Thomas Parker, Limited, are at Wolverhampton.

Scientific Instruments.—We have received from Messrs. John Davis and Son, of All Saints' Works, Derby, and 118, Newgate-street, E.C., a catalogue of various scientific instruments made by them. These include the Henderson patent traverser, and the Ogle protractor, theodolites, miners' dials, anemometers, miners' safety lamps, engine counters, speed recorders, pressure and vacuum gauges, planimeters, and drawing instruments.

The Singapore and Hong-Kong Cable.—The Eastern Extension, Australasia, and China Telegraph Company, Limited, have completed the laying of the first section of their alternative cable between Singapore and Hong-Kong—namely, between Singapore and Labuan. In addition to affording direct telegraphic communication with Labuan, this line practically brings British North Borneo into telegraphic communication with the rest of the world.

Rouen.—Eleven tenders have been sent in for the electric lighting of the port of Rouen. The lowest was by the Société Alsacienne, which amounted to 54,835f., or, say, £2,193, and the highest was by the Etablissements Cail, which amounted to 125,000f., or, say, £5,000. Application has been made by a company formed by M. Pitot, a local banker, for a concession for a system of electric tramways. It is proposed to use accumulator cars.

The Future of Gas.—A paper was read last week before the Society of Arts, by Prof. Vivian B. Lewes, on "London Coal-Gas and its Enrichment." At the close of the discussion, Mr. J. Norris Pimm, who presided, said he believed that in the future gas would be used more for motive power and heating purposes than for lighting. He had an electric light installation in his own house, but his gas bill was more than it used to be, gas being used as the means of producing electricity.

The Late Henry Giffard.—In his will the late M. Henry Giffard made the State his residuary legatee, with instructions to utilise what remained of his fortune, after payment of special legacies, for useful foundations, prizes, etc. A sum of 100,000f. has now been given from this bequest to the Société Internationale des Electriciens, to be employed in the construction and management of a special pavilion at the central laboratory, under the condition that it bears the name of Henry Giffard upon it.

Stirling.—The subject of the electric lighting of this town, to which we referred in our last issue, continues to receive the attention of the Municipality. At the last meeting of the Town Council letters were read from two

Digitized by Google

electric lighting companies with regard to supplying the town. It was agreed to acknowledge receipt of the communications, and remit to the Electric Light Committee to obtain all necessary information in view of the Council applying for a provisional order in November.

Killarney.—A curious state of affairs exists here in connection with the lighting of the streets. A majority of the Commissioners on the Municipal Board gave the public lighting to the Killarney Electric Light Company, whose contract commenced on Saturday last. The gas company also lighted up as usual, and it is stated will continue to do so until the matter is settled in a court of law. Killarney consequently presents a remarkably brilliant appearance. It remains to be seen who has got to pay the piper.

No Hocus-Pocus about It.—"There is no hocus-pocus about it," Prof. Ayrton remarked during the course of the reading of the paper before the Institution last week on "Transparent Conducting Screens for Electric and other Apparatus." He was standing at the side of an electromagnetic voltmeter with a white handkerchief in his hand. "I shake the instrument with my handkerchief and it reads 100 volts. I now connect it with the mains of the Westminster Company, and shaking it, it reads 40 volts, whereas the current in the mains is at 100 volts."

Gas and Electricity.—At the half-yearly meeting of the South-West of England District Association of Gas Managers, held at Salisbury, on Tuesday, a general opinion was expressed that, so far from the electric light having been a detriment to gas consumption, its introduction had really acted as a stimulus to managers and companies to increase the business, and perfect the utility of gas in every possible way. It is satisfactory to note that gas managers are discovering now that the electric light is not an enemy to them, but a friend. This is what we long ago pointed out to them.

Ichabod.—Serious fears have been entertained by Gog and Magog that the hoary fame of London town would be tarnished, if not absolutely obscured. Men wearing fustian and having short black pipes have busied themselves during these past few weeks or months with pick and shovel in rooting up the iron gas-lamp pillars that have lined the City thoroughfares for so many years. Now the only available sources of light on the streets are these long-legged, ghastly gallows posts with dazzling electric imps shut up in glass cases on top of them. Ichabod! for the glory of gas has departed.

Large Transformers.—A large order for transformers has been given out by the Cataract Construction Company to be used in the plant of the Pittsburgh Reduction Company at Niagara Falls. The apparatus will transform the two-phase current delivered from the station of the Cataract Company at 2,500 volts into continuous current at 160 volts for the use of the Reduction Company. There will be eight 200-kilowatt step-down transformers and four 370-kilowatt revolving transformers for transforming two-phase current into continuous current. It is believed that this will be the largest plant of the kind in the world.

Nuremberg.—In our last issue we referred to the fact that the street tramway company were waiting for the authority of the Municipality to construct an electric tramway system. The Municipality has now authorised the construction of an experimental line on the route from Maxfeld to the central railway station and the Plärrer head depôt, the experimental period not to exceed a year. It is also stipulated that the lines shall be built to the suburbs of Steinbühl and St. Johannis. The Municipality demands 2 per cent. of the gross receipts and a division of profits beyond 5 per cent. The tramway company estimate the cost of the introduction of electric traction at about 1,800,000 marks, or, say, £90,000.

Telegraph Material for India.—In the House of Commons on Monday, Mr. H. Fowler, in answer to Colonel Howard Vincent, said that competition for the supply of telegraph material for the Indian Telegraph Department and other branches of the India Office was not restricted to specially favoured houses. Any British or Irish firm that could satisfy the department of its ability to supply goods of the quality required would be placed on the India Office list of contractors, and would be invited to tender as opportunity arose. Experience had shown that it was not advisable to purchase stores of this description by public advertisement.

Patent Office Fees.—In the House of Commons last week Mr. A. C. Morton put a question on the subject of Patent Office fees. In reply, Mr. Mundella said that the number of applications refused by the law officers between July 1, 1852, and December 31, 1883, could not be given, no record of such refusals having been kept. The number refused by the comptroller of patents between January 1, 1884, and December 31, 1893, was only 146, and the value of the fees accruing to the Patent Office therefrom about £500. The number of patents voided, at one stage or another, through non-payment of renewal fees between July 1, 1852, and December 31, 1893, was 121,242, but no fees accrued to the Patent Office by reason of their expiry. The average life of a patent during the period named was about five years.

Electric Transmission of Power in Belgium.—The success of the installation at the Herstal Arms Factory at Liège, where the whole of the machinery is driven by electromotors, has given an impetus in Belgium to the industrial application of electric transmission. The Société de la Vieille Montagne, which at present have several steam-power installations at different parts of their works, are going to abolish them, substituting one large central station, from which power will be transmitted electrically to where it is required. It is expected that this arrangement will result in economies being effected. M. Pieper, of Liège, is at present arranging a railway carriage of the Belgian State Railways in order to make experiments in connection with electric traction on railway lines of the standard gauge.

Mix and Genest.—The annual meeting of the shareholders of the Actien-Gesellschaft Mix and Genest, of Berlin, took place on Monday, when the report was submitted and adopted. The result of the year's trade showed a gross profit of £17,435, and after writing off £3,910 for depreciation of plant, etc., and carrying to a reserve fund £500, the directors were able to declare a dividend of 8 per cent. on the paid-up capital. The constantly increasing business of this company has necessitated the building of a new factory, as the orders, more particularly for telephone exchange work, have required the renting of two additional factories. The new building has been designed with a view to centralise the manufacturing department, the estimated cost being £30,000, and the cost of acquiring the site, which is 6,653 square metres, is £17,000.

E.C. Company.—We are informed that the reorganisation of the staff at the works of the E.C.C. is now complete. Mr. A. B. Blackburn, M.I.C.E., late with Messrs. Mather and Platt, Limited, has been appointed to succeed Mr. T. Parker, and the work is going on as usual. Several important contracts have been lately booked by the company, and they are proceeding with the contracts for lighting Wolverhampton, Halifax, and Aberdeen. They have also just received the order for the electrical plant for Stafford, and have instructions from

Digitized by Google

the County of London and Brush Provincial Electric Lighting Company to proceed with the plant for the Clerkenwell central station. We understand that the changes which the Board felt necessary to be carried out have all been for the interests of the company, and that the directors are confident that they will lead to economy and prove beneficial.

Coal-Mining by Electricity.—A series of trials of electric coal-cutting machinery has taken place this week at the Lidgett Colliery, Tankersley. Recently Messrs. Robert and Thomas Clarke, sons of Dr. Clarke, owner of the colliery, invented a coal-cutting machine to be driven by electricity. Subsequent trials were satisfactory, and the colliery company felt they would be justified in putting down suitable plant. On the pit bank is a pair of engines for driving a dynamo, and the current generated is conveyed underground to the machine, a distance of about a mile. The trials were made with a machine having a "cutting wheel" about 4ft. diameter. At the first day's trials the machine "holed" 40 yards of coal face, 40in. underneath, in a little over an hour. On Wednesday the work was even more satisfactory, the machine cutting 10 yards, 40in. deep, in 12 minutes, and when certain contemplated improvements are made, it is expected that it will cut a yard per minute. The trials were conducted by Mr. R. Clarke, Mr. Stevenson (electrical engineer), and Mr. Thompson.

Some Phenomena of the Upper Air.—At a meeting of the Royal Meteorological Society held on Wednesday, Mr. Richard Inwards, F.R.A.S., the president, delivered an address on some phenomena of the upper air. He said that there are three principal ways in which the higher atmosphere may be studied—(1) by living in it on some of the great mountain chains which pierce many miles into the air in various parts of the globe; (2) by ascending into it by means of balloons; and (3) by the study of the upper currents as shown to our sight by the movements of the clouds. Mr. Inwards said that whatever system of naming and classifying clouds be adopted, it should depend on the heights of the various clouds in the air, and he gave a few rough rules by which the comparative altitudes of the clouds may be judged when there is no time or opportunity to make exact measurements. Among the indications by which a cloud's height in the air may be gathered are its form and outline, its shade or shadow, its apparent size and movement, its perspective effect, and the length of time it remains directly illuminated after sunset. After showing a number of lantern slides illustrating the various types and forms of clouds, the aurora borealis, rainbows, etc., the president concluded his address by urging the desirability of establishing a good cloud observatory somewhere in the British Isles.

Photometry.—The third and last of the series of Cantor lectures on photometry was delivered by Captain Abney, C.B., F.R.S., at the Society of Arts on Monday. In his first lecture he had said that to get a constant light it was necessary always to have the same temperature throughout, referring, of course, to carbon lights only, and by means of the electric light and of the spectrum of the electric light he showed how this could be effected, using for the purpose an instrument which might be said to be of historic interest. This was the apparatus employed at the late eclipse for estimating the measurement of light of the corona—the method being that of the grease-spot. He next introduced another photometer, which he had himself devised. It was useful for a number of purposes, and he believed it to be original. The principal feature was the application of a screen in the form of a double cube, and by its means he had measured, amongst other things, the density of deposit on photographic negatives, and the amount of luminosity of coloured glasses, the light of a dark room, for instance. This led to the question whether the light reflected from surfaces could be measured, and he showed how this could be done in a simple manner, referring, as an example, to the measurement of the blackness of the image on the platinotype paper used in photographic printing. The light reflected from coloured surfaces could also be measured, and here we had the photometry of colour.

Electric Illumination.—The third lecture on this subject by Prof. Fleming was delivered at the Royal Institution on Tuesday. The lecturer commenced by describing the effects of age upon the light-giving qualities of incandescent electric lamps. He stated that, in general terms, a rise of resistance and decrease of candle-power were the results of changes taking place in the filament. Passing to the subject of arc lighting, he mentioned there were three modes of electric discharge—the incandescent discharge, the spark discharge, and the arc discharge. The two former modes pass spontaneously into the arc discharge if the pressure and quantity of electricity are great enough. The formation of an arc between carbon rods was then shown, and it was experimentally proved that the arc could not be started unless either the rods were first brought into contact or the insulating power of the air between broken down by an electric spark. An immensely magnified image of the arc was projected on the screen, so that its interior structure was rendered visible. It was seen, for instance, that the positive carbon rod becomes most intensely hot at the extremity and hollowed out into the form of a crater, from which about 80 per cent. of the total light is emitted. The negative carbon does not become so hot. The space between the two, or the true arc, is filled with vapour of carbon. In the central space a brilliant violet axis is seen, violet being the colour of incandescent carbon. Outside this is an aureole of carbon vapour of yellow or golden colour. With the use of a prism, the central axis of the arc gave a spectrum marked by two brilliant violet bands. It was next shown that the rise of electric pressure in the arc takes place chiefly at the surface of the crater, which is, in fact, the place where the work is done in evaporating the carbon. The light emitted is, therefore, due chiefly to the incandescence of the carbon in the crater. Hence the light is not given off equally in every direction. It is most intense in that direction in which the largest area of crater can be seen. The subject of arc lamp mechanism was then lightly touched upon, and a number of varieties of arc lamps exhibited in action. In conclusion, the lighting of streets by arc lamps was discussed.

Electric Cooking in the Metropolis.—As stated in our last issue, a series of demonstrations of electric cooking and heating has been commenced at the showrooms of the London Electric Supply Corporation, Belgrave-mansions, Ebury-street, under the auspices of Messrs. Crompton and Co. It appears that this is only the commencement of a new departure about to be made by the metropolitan electric supply companies, who propose to encourage the use of current for the purposes mentioned. With this object in view it is intended, according to a statement in the *Pall Mall Gazette*, to lease out to consumers electrical appliances in the same way as the Gas-light and Coke Company have done in the case of gas appliances. Mr. R. E. Crompton, who has been interviewed at the above address by a representative of that paper, gave some particulars as to cost. With regard to improvements since the Crystal Palace Exhibition, Mr. Crompton said: "We have spent thousands of pounds in experimenting and in rejecting before we really got the secret of the

Digitized by Google

thing, as I may say we have now. The Americans are generally supposed to have invented this notion, and we to have stolen it; but, as a matter of fact, we are miles ahead of anything they have got in America, and I fairly startled an American who came to see our things fresh from the Chicago Exhibition. He refused to believe his eyes. The most important discoveries we have had to make relate to the enamels in which the wires are bedded, and to certain dry processes of manufacture. It was thought to be impossible for a long time to get an enamel that would resist the very high temperatures required without softening. We have found one at last, and now we use three kinds of enamel. First of all, a coating of the hardest enamel is laid on the iron plate, and the little conducting wire is spread upon it. Then a second coat of enamel, not quite so hard, is laid over that, and, finally, a coat of decent white enamel is spread over all. The difficulty used to be to put on the second layer without melting the first, and allowing the conductor to sink through and touch the iron plate. Another important change we have made is the substitution of nickel-steel wire for copper or some other metal, which was used at first. But the thing which has really settled the business and made the industry a practicable one is a method we have devised for crimping and laying on the fine wire by machinery on to a dummy plate and so transferring it bodily to the enamel. Formerly it used to be laid on by hand, a difficult matter at the best, and most trying when you are dealing with hot layers of liquid enamel. Now we have got over this, electric cooking apparatus is as easily made as tinware."

Some Properties of the Electric Discharge Through Gases.—A discourse on this subject was given last Friday at the Royal Institution by Prof. J. J. Thomson. His first experiments were devoted to showing the reluctance of the electric discharge to pass from a gas into a metallic electrode. In one of the experiments by which he illustrated this a bulb was employed into which two long electrodes projected. The discharge between these was not from point to point, but from the point of one to the base of the other, the electricity keeping in the gas as long as possible. He then showed how the states of electrification in a bulb through which an alternating current is being passed vary according to the gas and electrodes used. Oxygen gives a strong positive electrification, while with hydrogen it is different in different parts of the bulb. The discharge from an electrode of oxide of copper in hydrogen is negative till the oxide is reduced, when it becomes positive. Such results seem to afford some support to a theory of the fundamental identity of chemical and electrical action. Prof. Thomson then went on to consider the discharge through gases without metallic electrodes, and for this purpose used the rapidly alternating current which flows in a wire connecting the outsides of two Leyden jars, the insides of which are connected with a Wimshurst machine. This wire was made into a coil, in the centre of which were placed bulbs containing the gases to be experimented upon. When two gases were to be compared in respect of conductivity, etc., the wire was made into two coils, in one of which the gas to be tested was placed and in the other a standard bulb. The brightness of the discharge in the latter gave an indication of the amount of energy absorbed by the former, or, in other words, of its resistance. From this and other experiments resembling those of Mr. Tesla, the lecturer deduced the conclusion that the conductivity of gases at a certain degree of rarefaction is greater than that of any metal, and almost infinitely greater molecule for molecule. At a higher degree of rarefaction, however, conductivity is diminished, and in a perfect vacuum, as has been shown by some of Prof. Dewar's experiments, it is probable that the discharge would not pass at all. Prof. Thomson showed that when a vacuum bulb was enclosed in a vacuum jacket which had been made with mercury and the whole apparatus placed inside a coil, the discharge occurred only in the inner bulb. But upon increasing the density of the mercury vapour in the annular space the discharge took place there instead of in the inner bulb. Whatever deduction may be made from this experiment it is clear that the annular space in both cases is permeable by electric force—in other words, that electric currents cross a high vacuum quite freely, though they produce no glow to indicate the fact. The last experiment performed referred to the influence of a magnetic field on the discharge, which was shown to take place more easily along the lines of magnetic force that across them.

The Hamburg Electric Tramway.—As we have already briefly noted, the circular electric tramway at Hamburg was set in operation a short time ago. It was originally intended that the work should have been completed in November last, but the difficulties in connection with the project were greater than had been anticipated, so that delay ensued. Running was commenced at the end of February, and a month later the Union Elektricitäts Gesellschaft of Berlin, which had carried out the work, invited a large party of tramway men and others to inspect the line, an account of the visit appearing in the *Elektrotechnische Zeitschrift*, from which we obtain the following particulars. The line is constructed on the well-known Thomson-Houston system, which has already been employed in Germany on the Bremen line. At present only the circular tramway is operated electrically, but very shortly two further lines will be equipped. The circular line, which surrounds the old town, is nearly five miles in length, and contains some steep gradients, sometimes as high as 1 in 15. The line is of double track throughout, and there is a five minutes' service in each direction. There are 14 cars in use, making a total of 308 journeys per day. Copper conductors, 8·25mm. in thickness, are carried 20ft. above the tramway lines and longitudinally therewith. These are suspended by insulators to transverse steel wires which are supported either by iron posts, or in narrow streets from the houses. In the newly-widened street at the harbour, however, ornamental posts have been erected between the tracks, which carry arms on each side supporting the copper conductor. The street lamps here have also been placed on these ornamental posts. Where many telephone wires cross the street, the conductor is surmounted by a small protecting wooden roof, the reason being that shortly after the opening of the electric railway a telephone wire gave way, fell on the conductor, and caused a short-circuit. Current is received from the central station in the Poststrasse, which also supplies current for the lighting of the town. The central station furnishes lighting current on the three-wire system at 300 volts pressure, but the tramway requires current at 600 volts. Therefore two Schuckert transformers of 170 h.p. have been installed at the central station, and there has also been erected a 170-h.p. steam-engine directly connected with a dynamo made by the Union Elektricitäts Gesellschaft. The cars run from seven in the morning until midnight. Each car is lighted by five incandescent lamps inside. The carrying capacity of each car is 30 exclusive of driver and conductor. When the two new lines from Vaddel to the Schlump, and from the Pferdemarkt to Eimsbüttel are opened, the total length of electric line will be about 13 miles. Both the new lines will, on part of the route, traverse portions of the circular line. The tramway company is working the line on its own account, but has certain guarantees from the Union Elektricitäts Gesellschaft.

ELECTRIC TRACTION ON LONDON RAILWAYS.

BY FRANK B. LEA.

(Concluded from page 436.)

We have said that there are, roughly speaking, five great railway systems in the metropolitan area upon which the shuttle or circular form of passenger traffic may be found to some considerable extent, and it will, perhaps, be advantageous at this point to set them forth in such detail as will be useful and expedient, having in view throughout the question of possibly substituting electric working for steam traction upon these lines with some reasonable amount of success. It need hardly be said in reference to this that the cost of conversion, and the estimated monetary value of benefits accruing from improved methods, will prove the main factors in any decision to be reached.

I.—UNDERGROUND SYSTEM.

Lines.	Weekday trains daily each way.	Working hours.	Average equivalent service, each way.
A. Circle trains:			
King's Cross, Aldgate, Charing Cross, Kensington (High-street), and *vice versâ*.	—	—	10 min.
B. Shuttle trains:			
1. New Cross to Putney and Wimbledon.	73 west	5.30 a.m.	20 min.
	73 east	12.30 a.m.	
2. New Cross to Richmond, *vid* Mansion House.	31 west	5.50 a.m.	30 min.
	28 east	12.30 a.m.	
3. Whitechapel to Ealing, *vid* ditto.	63 west	5.30 a.m.	20 min.
	58 east	12.50 a.m.	
4. Aldgate to Mansion House, *vid* Addison-road (Outer Circle).	39 west	5.45 a.m.	30 min.
	39 east	12.50 a.m.	
5. New Cross to Richmond, *vid* King's Cross.	80 west	5.15 a.m.	15 min.
	78 east	12.30 a.m.	

II.—METROPOLITAN EXTENSIONS: NORTH AND SOUTH.

1. Moorgate-street to Victoria, *vid* Brixton (L.C. and D.R).	71 west	4.0 a.m.	20 min.
	69 east	1.0 a.m.	
2. Moorgate-street to Crystal Palace (high level) and Greenwich, *vid* Nunhead.	62 south	5.0 a.m.	20 min.
	58 north	12.45 a.m.	
3. Victoria to ditto, ditto.	30 west	6.10 a.m.	40 min.
	27 east	12.45 a.m.	
4. Moorgate-street to Clapham Junction.	12 west	7.50 a.m.	Hourly.
	13 east	8.30 p.m.	
5. Moorgate-street to Tottenham and Hendon (Mid. R.)	81 south	5 a.m.	15 min.
	80 north	12.45 a.m.	
6. Moorgate-street to Alexandra Park (G.N.R.).	27 south	7 a.m.	30 min.
	31 north	12.45 a.m.	
7. Woolwich to Finsbury Park (S.E.R.).	9 each way	5.30 a.m.	1½—2 hours.
		11.15 p.m.	
8. Ludgate-hill to Richmond and Wimbledon (L. and S.W.R.).	27 west	6.50 a.m.	30 min.
	27 east	10.30 p.m.	

III.—NORTH LONDON.

1. Broad-street to Mansion House and Richmond, *vid* Hampstead and Willesden.	74 west	5.15 a.m.	15 min.
	74 east	11.45 p.m.	
2. Broad-street to Chalk Farm.	—	5.30 a.m.	15 min.
		12.15 a.m.	
3. Broad-street to Bow and Poplar.	—	5.15 a.m.	15 min.
		12.30 a.m.	
4. Broad-street to Alexandra Park (G.N.R.).	15 south	7.15 a.m.	45 min.
	19 north	8.45 p.m.	

IV.—GREAT EASTERN: SUBURBAN LINES.

1. Liverpool-street to New Cross and Peckham Rye, *vid* Wapping	49 south	4.50 a.m.	20 min.
	49 north	11.45 p.m.	
2. Liverpool-street and Fenchurch-street to North Woolwich	85 west	5 a.m.	15 min.
	90 east	1 a.m.	
3. Fenchurch-street to Blackwall.	—	5.20 a.m.	15 min.
		12.30 a.m.	

V.—SOUTH LONDON.

London Bridge to Battersea Park and Victoria, *vid* Peckham	66 west	4.45 a.m.	20 min.
	70 east	12.45 a.m.	

The lines and routes thus detailed, though with a confessedly imperfect classification, are such as appear from their traffic to be most suited for electric working throughout the London suburbs; and where others might, perhaps, be thought equally fit for inclusion in the list, it will be found either that the traffic is unimportant or infrequent, or else that main-line working demands the first consideration. This latter point would prove an almost insuperable difficulty with regard, say, to the South-Eastern, Brighton, South-Western, Great Eastern, Great Northern, and other main-line suburban services other than those already included; and even on many of the routes in the table, obstacles might arise in this way. For instance, express main-line traffic is worked to some extent upon systems II. 1, II. 3, II. 5, II. 8, and would have to be allowed for accordingly. It might even prove impossible to arrange such joint working; for obviously in the cases above mentioned, the companies interested would consider that a breakdown of the electric service might at any time seriously affect their main-line traffic.

The London, Chatham, and Dover expresses from Victoria through Brixton, the Midland trains through Kentish Town, and the Brighton Company's Portsmouth services would all be running for short distances upon lines also used by trains which might advantageously be operated by electric motors. Complete separation of the fast and slow traffic is, of course, desirable, but the difficulty and expense of building even a single additional line must prove in many cases almost prohibitive. In this connection, it seems quite time that some capable engineer should take in hand the planning of a double-decked system, by means of which the capacity of many lines now overcrowded might be nearly doubled without going to the enormous expense of buying fresh land in populous suburbs. A successful instance of this type of line is to be seen in the Liverpool Overhead Railway, where a surface railway runs underneath the superstructure for nearly its entire length.

Turning, now, to the table of systems shown, it will be seen at once that, with the exception of the Inner Circle trains running every 10 minutes, the headway between trains on any particular route is by no means short, the average number of trains all round not being really more than about three per hour. Of course, the reason for this will also be obvious: it is due simply to the fact that certain parts of the route are used by several services, and the trains must therefore be sandwiched or fitted in one after another in the most convenient way. An observer watching the trains that pass eastward through, say, Blackfriars Station, on the Inner Circle, will not have to wait more than five minutes at the outside to count each train; the average will be nearer three minutes. At such points the lines are fully crowded, and the remedy—if a better and more frequent service is desired—is twofold: either the lines must be doubled—a practical impossibility on account of the cost—or else greatly improved methods of working the traffic must be introduced.

This may be done in two ways with a material saving of time. By the use of electric traction a much higher average speed may be maintained, judging from the experience gained on the Liverpool Overhead Railway; this, of course, is partly due to the greater ease of starting and stopping when a rotary motor is employed. The corresponding economy in fuel, etc., is by no means an unimportant consideration, but need not be dealt with here.

Secondly, a materially diminished headway between the trains is obtainable by the use of automatic electric signalling, instead of the ordinary manual system of operation. Here, again, is a great saving in money as well as time; but we are at present dealing more especially with the latter. So far as the underground lines are concerned, it appears pretty evident that if the services now being operated—as shown in the table, on a 20 or 30 minute headway—are to be materially quickened, this result can only be accomplished by the use of electric traction and automatic electric signalling. Similar remarks would apply to the lines which form the extensions of the Metropolitan Railway through Snow-hill to the South of London, and in all cases, indeed, where a number of distinct services are obliged to use the same lines, even over a short distance.

Where a route is more or less isolated—as, for instance, Fenchurch-street to Blackwall—the question resolves itself rather into deciding upon the relative advantages of light trains at frequent intervals, or heavier trains on a longer headway. Of course, a high efficiency of electric traction is best obtained with services running, say, two or three car trains every five minutes, rather than nine-car trains at intervals of a quarter of an hour—that is, to make the line a tramway rather than a railroad. For suburban service, where frequent stops are required, one would say that this tendency is right and proper, and deserves to be fostered.

Questions of cost—either as regards capital outlay or working expenses—are not now touched upon in any way.

Digitized by Google

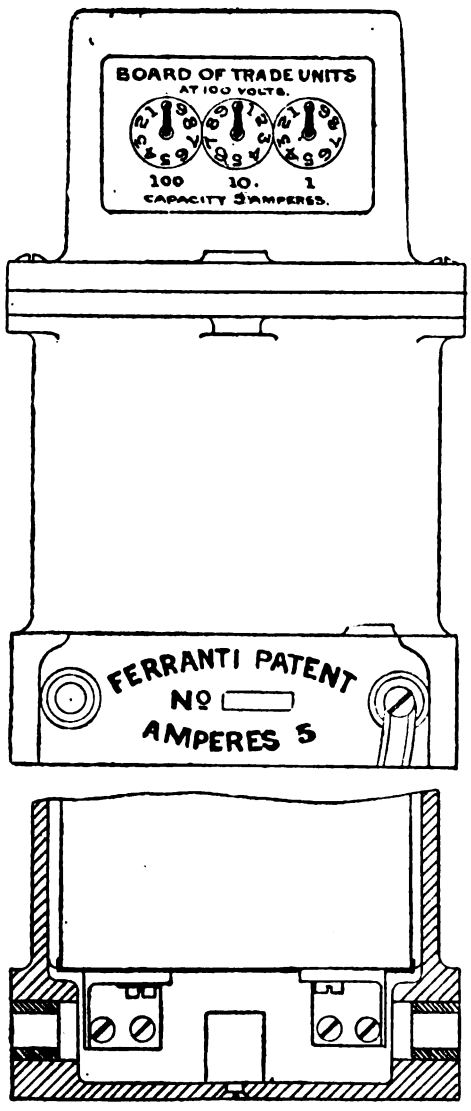
When the time comes for engineers to submit estimates, it may be taken for granted, however, that they will be ready to convert these or other lines, and operate them, if required, on a basis which will show considerable economy of working over the present systems, whilst the monetary value of increased public ease and comfort will represent by no means a small percentage upon the capital expenditure required for the proposed change.

ELECTRICITY METERS.*

BY R. P. WILSON.

(Continued from page 439.)

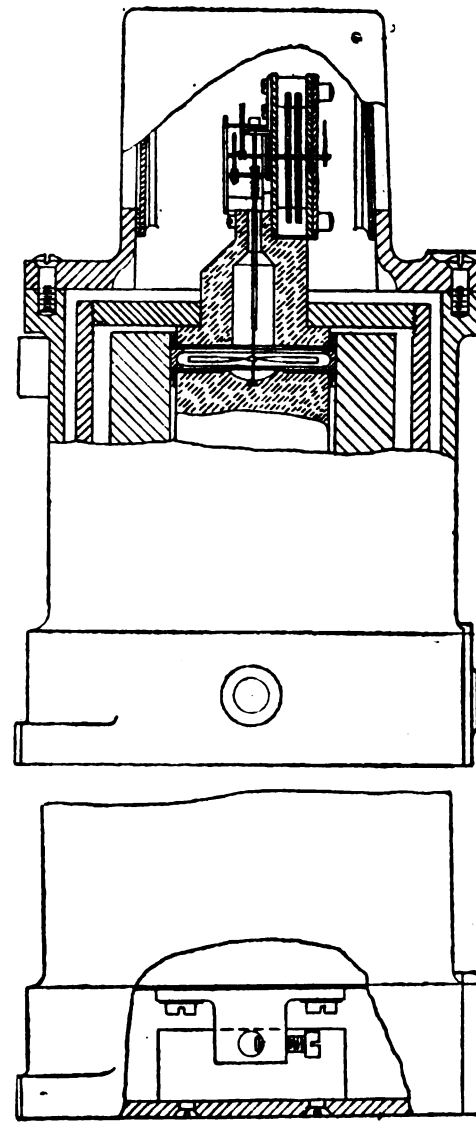
(3) *The Shallenberger Alternating-Current Ampere-Hour Meter.*—This meter, which is the invention of Mr.



Ferranti Meter.

Shallenberger, one of the engineers of the Westinghouse Company, is one that has undergone probably less modifications than other meter in the market, excepting the Edison. Its action may be explained as follows: The current to be measured passes through the series coils, inside which is what may be described as a short-circuited secondary coil fixed with its axis at an angle of about 45deg. from that of the series coil. Enclosed in both these coils is a soft-iron ring mounted horizontally on a vertical shaft. The current in the series coil induces in the short-circuited secondary another current, in which the current lags a quarter of a period, with the result that these currents, which are continually reversing, produce rotation in the iron ring, which communicates its motion to the registering mechanism. In this meter the velocity attained is approximately proportional to the square of the speed, and the square root is extracted by the resistance offered by the air to the revolution of a four-winged aluminium fan mounted at the lower extremity of the shaft. It may be well to point out that the retardation produced by any such fan varies with the barometric pressure—that is to say, with the density of the atmosphere. The meter, however, is very largely used with very satisfactory results, but only in comparatively small sizes, as far as the author is aware.

(4) *The Ferranti Direct-Current Meter.*—The rotation of this meter is produced by passing a current radially through a bath of mercury situated in a magnetic field. Immersed in the mercury is a fan attached to a vertical shaft, which communicates its rotation to the registering mechanism. The torque produced by the current in the series coil which is used to establish the magnetic field above referred to and



Ferranti Meter.

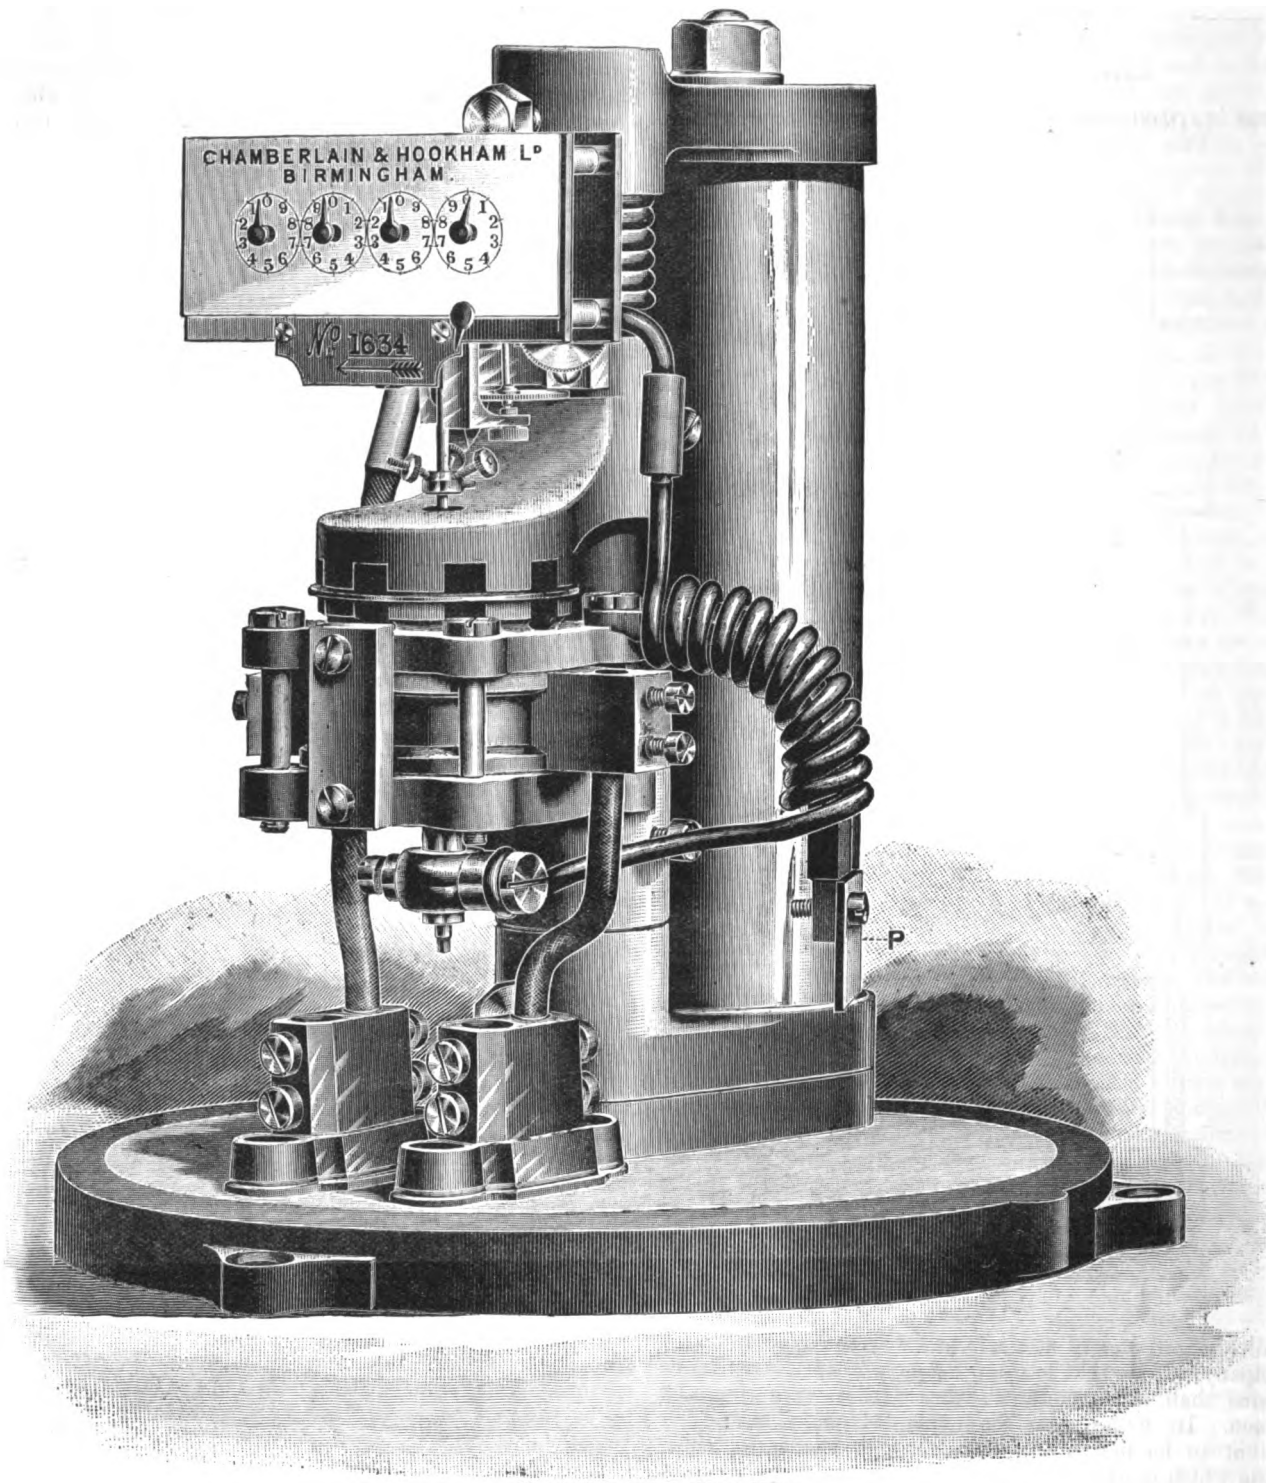
to pass through the mercury, would produce a rotation whose velocity would be proportional to the square of the current. This is retarded by means of the fluid friction set up by the moving of the mercury against the side of the vessel containing it; this fluid friction corresponds to the fans in the case of the Shallenberger meter. A meter on this principle was originally invented and exhibited by Lord Kelvin at the Health Exhibition. Since that time Mr. Ferranti made, with a certain amount of success, some alternating-current meters on the same principle, but they were not commercially as successful as the direct-current type, and have since been abandoned. The initial friction in this meter is counteracted by making the core of the solenoid on which the series coil is wound a permanent magnet, which takes the place of a shunt circuit such as is generally used. A great deal of difficulty was experienced in getting mercury that was chemically pure, and in preventing the rusting of the steel shafts, but the author has been given

* Paper read before the Northern Society of Electrical Engineers, April 9, 1894.

Digitized by Google

to understand that these difficulties have since been overcome by methods which Mr. Ferranti is evidently anxious to keep to himself, as a request for further information on this subject elicited no reply. These meters are manufactured in a very neat compact cast-iron case, and they were the first to contain the double sealing arrangement which, although suggested by the Board of Trade, had been adopted by Mr. Ferranti before that time.

(5) *Chamberlain-Hookham Meter.*—The older form of this meter was very similar in principle to the Thomson, in that the retarding arrangement consisted of a copper disc revolving between the poles of a permanent magnet. The motor part consisted of a number of coils wound flat and fixed to the copper disc, the current being carried to the armature coils by means of a commutator rotating in mercury-cups. The action of the instrument was thus a motor in which the armature carried the current to be measured, and a constant field in the form of a permanent magnet. This form of meter has, however, been entirely superseded by the new type, which is almost a different meter altogether. Like the Ferranti, it consists of a mercury-bath carrying a disc through which the current to be measured travels radially, the intensity of the field being varied by a series coil wound on one of the cast-iron polar extensions, and a further winding wound on an iron bar attached to the cover of the bath, so that the total induction through the permanent magnets remains practically unchanged. A very ingenious device for reducing the friction of the rotating disc consists of attaching to the disc immersed in the mercury a second disc of vulcanised fibre,



Chamberlain and Hookham Meter.

which, owing to its small specific gravity compared with that of mercury, tends to reduce the weight on the lower bearing. The difficulty of rendering permanent the magnets so largely used now in this and other meters has been practically overcome, so that there is no objection to their use.

Before leaving the subject of meters altogether, it may be well to mention the Ferranti-Wright meter, but as this meter is not very largely used it will be unnecessary to devote more than a very few words to it. The series coils

Digitized by Google

and shunt coils are wound on cores of laminated wrought iron having elongated polar projections, between which is placed a closed metallic ring. The progressive poles in these elongated pole-pieces alternate successively, and thereby produce rotation in the conducting disc which is proportional to the square of the current, the retardation being induced by means of a fan, as already explained. This meter depends for its action partly on the hysteresis in the iron, and partly to the reaction of the current in the metallic ring revolving between the poles.

(To be continued.)

A NEW WIND MOTOR FOR ELECTRIC LIGHTING PURPOSES.

An exhibition was made at Willesden Junction on Tuesday afternoon of the Rollason wind motor, an appliance intended for the operation of dynamos for electric lighting and power purposes. A large party of guests assembled in response to invitations issued by the

directors of Rollason's Wind Motor Company, Limited, of 13, Berners-street, to witness the motor at work, but as the wind was unfavourable the motor could not properly be shown in action. Previous to the demonstration of the motor, luncheon was served at the Royal Oak Hotel, Harlesden, when Mr. Fletcher and Colonel Brown, two of the directors of the company, expressed themselves very sanguinely as to the possibilities of the appliance. It was mentioned, in so far as the electrical arrangements are concerned, that Messrs. Edmundsons, Limited, of 19, Great George-street, Westminster, had co-operated with the company in bringing the Rollason system to its present position. The motor, which is arranged in a field close to the Junction, has been erected for about two months, and its efficiency, although no figures were forthcoming, is claimed to be high.

Observed from the train, the motor presents somewhat the appearance of an elevated bandstand. Its form differs materially from the ordinary method of constructing windmills as seen in rural districts, and from the type of windmill used experimentally for electric lighting purposes near the Cap de la Hève, on the French coast, or in the United States. The Rollason system may be divided into two parts—the mechanical arrangements of the wind motor, and the electrical plant and accessories. As far as the electrical portion of the system is concerned, the special features claimed are the methods adopted for disconnecting the dynamo from the accumulators when the wind drops, for charging and lighting simultaneously, and for stopping the dynamo when the accumulators are fully charged and for restarting it as soon as any current is taken from the accumulators. The object of this is to allow the combined motor and electrical plant to work all night without any attention. The details of these arrangements form the subject of pending patent rights, and of which little can be said at the moment.

With regard to the motor—an illustration of which is annexed—it will be noticed that it is a horizontal arrangement contained in a skeleton turret. From the top to bottom of the centre or axis of the turret is provided a vertical steel shaft; this has attached to it five concave sails, which revolve on radius rollers immersed in oil. On these sails are fixed a number of inclined ridges or planes, which it is claimed deflect the force exerted by the wind to their peripheries. Between the sails and the shaft is arranged a considerable open space which allows the wind to actuate simultaneously three sails out of the five. Outside the sails is a framing, or screen, supported by six radial or cross arms, which are bolted to a centre bearing, which is free to rotate independently of the sails. A second vertical shaft from the top of the shield is continued through the roof of the turret, and to this is fixed a vane, so that when the direction of the wind changes, it moves the shield into the correct position for only the concave sides of the sails to catch the wind. On the top of the sail shaft is fixed a cup containing a quantity of oil, within which are rollers, by which the shaft actuates the shield. The weight of the vane shaft is carried on an independent roller bearing fixed in the roof of the turret. The whole weight of the sails and framing carrying the shield is thrown to the centre bearings on the bottom of the turret, which thus gives to the working parts of the motor the desired balance.

The motor at the Junction is 20ft. in diameter, and is erected on an open iron structure 30ft. high. The power developed by the motor is transmitted by a vertical shaft running down the centre of the supporting framing into a wooden shed on the ground. Suitable gearing is provided on the lower end of the shaft for working the pulleys actuating by belting an Elwell-Parker dynamo, which is used to charge accumulators.

The company claim for the Rollason motor simplicity, efficiency in working, and that it can be left working for a lengthy period without any attention.

THE JOEL ALTERNATING-CURRENT MOTOR.

The alternating-current motor devised by Mr. Joel was illustrated and described in the *Electrical Engineer*, June 2, 1893. This motor has been tested at the Electrical Standardising, Testing, and Training Institution by Mr. H. E. Harrison, who has prepared a report on the efficiency of the motor. The following is a copy of the report, dated April 16, 1894.

"In accordance with your instructions, on the 12th inst. we took the readings, which are given in the table below. The alternating-current motor from which the results were obtained, was in each case run under the conditions arranged by your representative. The readings were taken by ourselves, and the instruments were afterwards compared with our standards.

Revolutions per minute.	Watts.	Electrical horse-power.	Brake horse-power.	Percentage efficiency.
1,582	1,160	1·55	0·454	29·2
1,390	999	1·34	0·354	26·4
1,263	950	1·27	0·316	24·8
1,259	950	1·27	0·314	24·7
1,296	877	1·17	0·420	35·7
1,324	877	1·17	0·429	36·6
1,490	900	1·20	0·482	40·0
1,472	950	1·27	0·477	37·6
1,506	1,020	1·365	0·465	34 0

"The motor is self-starting, and can be reversed by means of an ordinary reversing switch. The starting torque measured with the armature at rest, is $3{\cdot}925 \times 10^7$ C.G.S. units as compared with $2{\cdot}257 \times 10^7$, the torque when the motor is running so as to give 40 per cent. efficiency."

A BRILLIANTLY-LIGHTED AVENUE.

About a year and a half ago the low-tension system of street-lighting was introduced for the first time in New York on Fifth-avenue. It had been found, the *Electrical World* says, that some such device must be resorted to, for series arc lamps were little demanded on that avenue for commercial purposes, and the expense of laying the wires for conduits for street-lighting alone was so great as to be practically prohibitive. Accordingly the Edison Illuminating Company solved the difficulty very satisfactorily by employing a low-tension system, in which a pair of arc lamps on each post were used instead of a single lamp with dead resistance, as had been the case in previous attempts at low-tension arc lighting. Each of these lamps, which were of the Bergmann type, manufactured by the General Incandescent Arc Light Company, took five amperes at approximately 50 volts, so that practically the same amount of energy was used as in the high-tension arc lamp on the series circuit. The low-tension system also possessed a number of advantages over its older rival. In the first place, it was possible to connect the lamps directly to the Edison low-tension mains, thus effecting a great economy and adding to the convenience and flexibility of the system; secondly, the light was more effective on account of better diffusion, as the casting of shadows was practically obviated.

An ornamental post was employed made in three parts: the base, the shaft, and the arm section. Instead of placing the resistance in the hood of the lamp it was located in the base, and the lamps were lowered and raised from within the shaft, to which access was had by means of a door in the base, the key of which was carried by the trimmer. The lamps are fed by a sliding contact, so that when they are lowered the current is entirely shut off and the trimmer is perfectly safe from even a low-tension shock. The lamps are supplied from the mains by the ordinary house service method, wires running through the gas-pipe which forms the centre part of the shaft.

One of the great advantages of this system of lighting is the ornamental appearance of the posts and the lamps, which greatly surpass in this respect the older type of series lamp. This system has been found to operate most satisfactorily during the past 18 months, and the only criticism passed upon it was that the avenue was not as brilliantly lighted as had been anticipated. The Edison Company recently decided to overcome this difficulty by doubling the number of lamps, and accordingly have inserted at the centre of each block another post carrying two lamps. There are now 114 posts, which, with two lamps each, makes a total of 228 lamps. This has had the desired effect, and Fifth-avenue is one of the most brilliantly illuminated thoroughfares in the city. At the same time the light is much more soft and pleasing than that which is given by high-tension lamps.

A MODIFIED INSTRUMENT FOR THE DETERMINATION OF THE $\mathfrak{B}\,\mathfrak{H}$ CURVES OF IRON.*

BY H. W. SCHROEDER.

An article on this subject, which appeared in the *Electrical World* of February 24, 1894, called to my mind a very simple method invented by myself some time ago for measuring the relative permeability of different grades of iron.

I use a soft J-shaped yoke, between the legs of which is placed the piece of metal to be tested, and around which is wrapped the exciting coil. At the curved end of the yoke is placed a coil, which is connected to a voltmeter reading from one to one hundred volts—in fact, my instrument may be looked upon as a simple transformer, from which the primary core may be removed and replaced by the cores to be tested. We will treat it as such, and will call the coil surrounding the removable core the primary, and the coil at the bent end of the yoke, with which the voltmeter is connected, the secondary.

* From the *Electrical World*.

Now, it follows that if a piece of iron, the permeability of which is high, be placed between the legs of the yoke and used as a primary core, and an exciting current sent through the primary coil surrounding this, there will be a current induced in the secondary coil; and if this exciting current be increased until the voltmeter indicates 100 volts and be maintained constant, we can then replace our high-permeability core with one we desire to test. All the conditions now being the same as at first, except the primary core which we are testing, the voltmeter in the secondary will indicate in proportion to the number of lines of force cutting the secondary coil. The number of these lines of force depends upon the permeability of the metal being tested, and if the voltmeter now indicates but 75 volts we may know that the permeability of that piece of iron is but 75 per cent. of that of the first. Such an instrument as this is very easily constructed, the only part not readily at hand in almost any workshop or laboratory being a standard bar to compare with, but even this is not necessary where it is only wanted to determine the best of a few samples of iron. Of course, it is understood that an alternating current is used as an exciting current, and that any alternating-current voltmeter will do for use in the secondary.

I might add that where it would be inconvenient to maintain a uniform exciting current, two of these instruments (just alike) could be used, one for the standard bar and one for the iron to be tested, the primaries being connected in series, thus taking the same current. Two voltmeters would be used, one in each secondary, and compared directly with each other. For further accuracy, the standard to be tested could be changed from one instrument to the other and the voltmeters compared again.

AN ASTATIC STATION VOLTMETER.*

BY W. E. AYRTON, F.R.S., PAST-PRESIDENT, AND T. MATHER, ASSOCIATE.

The rapid development of electric lighting generating stations during the past three years has resulted in a greatly increased perfection in the regulation of the pressure, and consequently has created a need for measuring instruments of much greater precision than was previously required. At the same time, the powerful dynamos now employed, and the large currents that flow through the mains on the switchboards at these generating stations, has greatly increased the disturbing influences to which electromagnetic measuring instruments are subjected. Consequently, it is not to be wondered at that voltmeters and ammeters which answered fairly when the output of the stations was small have had to be discarded as being unsuitable for the present requirements. The authors have, therefore, been engaged for some time past in developing an electromagnetic voltmeter to fulfil the following conditions: (1) be unaffected by an outside magnetic field, whether uniform or not, and as strong as the disturbing magnetic field on any ordinary central-station switchboard; (2) be unaffected by an outside electrostatic disturbance, such as is produced on rubbing the glass front of the instrument; (3) have no temperature error; (4) have a high resistance, so as to measure equally accurately the true pressure at the end of long thin pilot wires, or in the station itself; (5) have a scale of large radius, and one very open at the working pressure, so that a small change in the pressure can be detected; (6) be dead-beat.

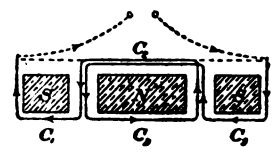

FIG. 1.

Condition No. 1 is most easily fulfilled by employing a powerful stationary permanent magnet and a moving coil, for such an arrangement has the great advantage that it cannot indicate a pressure unless a current be actually flowing through the coil; whereas soft iron and other types of voltmeters, when placed in a fairly strong magnetic field, may have the pointer deflected across the scale when no current whatever is passing through the instrument. But it is not sufficient to merely employ one permanent magnet and one moving coil, as is proved by the fact, which is probably not generally known, that the very beautiful Weston voltmeter, in spite of the permanent magnet being strong and the air-gaps in which the coil moves being extremely small, indicates slightly differently when put in different positions

* Paper read before the Institution of Electrical Engineers, April 12.

Digitized by Google

in a magnetic field even as weak as that of the earth's, the change in the reading being about ½ per cent. when the instrument is placed horizontally and turned through an angle of 180deg. in a horizontal plane.* This voltmeter therefore cannot, of course, give constant indications in a varying magnetic field 50 or 100 times as strong as that of the earth's. Now Messrs. Clark and Malpas have found, by experimenting with our portable magnetic field tester, that a field of 20 C.G.S. units, or one rather more than 100 times as large as that due to the earth, is the sort of magnetic disturbance that occasionally occurs on the switchboards of existing central stations, while fields of six C.G.S. units—that is, 30 times the earth's field—are quite common.

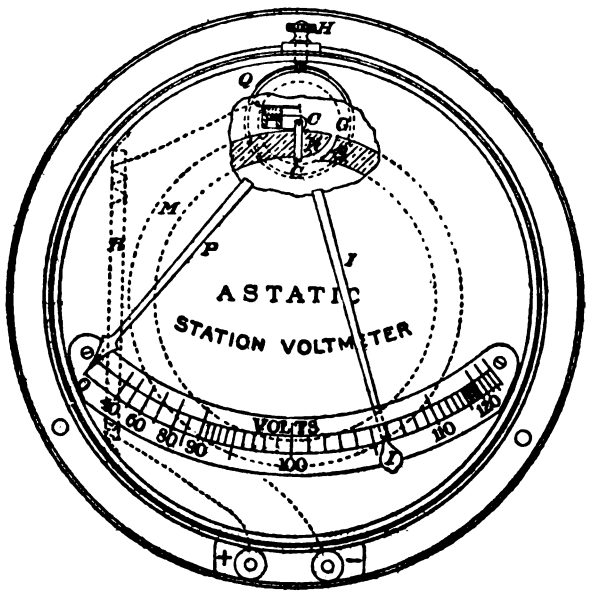

FIG. 2.

If the coil be wound astatically, and be acted on by two powerful permanent magnets inside the voltmeter, with their poles oppositely directed, good screening can be obtained from a uniform disturbing magnetic field; but errors will be produced if the disturbing field be non-uniform, such as is caused by a mass of iron, or by a conductor carrying a current, placed near the voltmeter. We have, therefore, carried this principle of astaticism further by employing three permanent magnets and a coil wound in three parts, as shown diagrammatically in Fig. 1, the area of the middle coil being double that of either of the end ones; and in this way we have obtained an arrangement which is comparatively unaffected by either a uniform or a non-uniform magnetic disturbance.

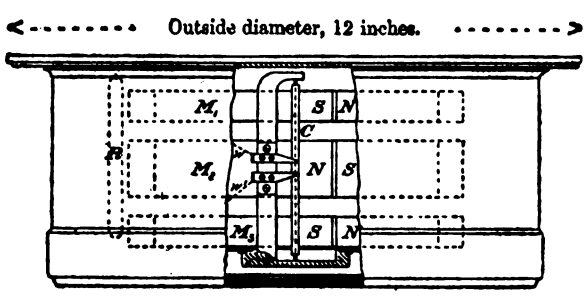

FIG. 3.

The moving coil principle also enables conditions 3 and 4 to be fulfilled, for the resistance of this 100-volt instrument is about 7,000 ohms; and as only 3 per cent. of this is composed of copper wire—viz., that wound on the moving triple coil—while 97 per cent. is of manganin wire, indicated by the stationary coil, R, in Figs. 2 and 3, the temperature error is practically negligible. This high resistance also causes the power required to actuate the voltmeter to be very small, not more than about 1½ watts being absorbed at 100 volts with this voltmeter.

The control is produced by a weight, because this is the method of exercising a controlling force that is least likely to vary, and because the objection to the employment of a gravity control—that the voltmeter cannot be used in any position—is of no importance in the case of a switchboard instrument.

Fig. 2 shows the voltmeter in elevation, while Fig. 3 gives a plan; both figures being drawn partly in section, so that the working parts may be more clearly seen. The triple coil, C_1, C_2, C_3 (Fig. 1), passes over the poles of the three magnets, M_1, M_2, M_3 (Fig. 3), the direction of the winding being such as to cause the deflecting forces for each portion of the coil to be in the same direction. The current is led up to and away from the coil by very thin flexible silver strips attached to the points of the stationary pieces, *w w'* (Fig. 3).

Conditions 5 and 6 are satisfied by specially shaping the air-gaps, and we find that without sacrificing the quickness of motion of the pointer, P, too much, we can flatten the calibration curve a the working part of the scale so that 1-100th part of a volt variation in the pressure can be detected.

A bit of the scale is seen in Fig. 4, and although large and bold an additional means for indicating whether the pressure is correct or not is provided by means of the index, I (Fig. 2). This index can be moved and set at any desired position by turning the milled head, H, which actuates a crown wheel segment, Q, carried by the ring to which the arm, I, is attached. This index arm is coloured red, while the pointer, P, and the arrow-head at the lower end of the index arm are coloured black. If the pressure be exactly right, the red index arm is entirely covered by the black pointer; whereas, if the pressure be high or low, red is seen to the left or right of the pointer respectively. An attendant can therefore see from a distance of many yards whether the pressure has exactly the desired value, or is above or below it. The same milled head, H, works the arrangement for clamping the moving parts during transport;

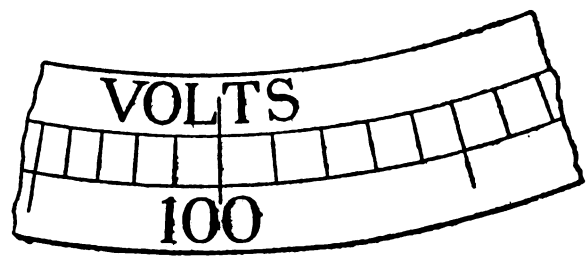

FIG. 4.

but this clamping device is so arranged that the moving parts cannot be clamped as long as the pointer is on any part of the graduated scale; hence there is no risk of the coil and pointer being accidentally clamped while the voltmeter is screwed up to the switchboard. To clamp the moving parts before removing the voltmeter, take out the two side screws that hold the voltmeter to the switchboard, and turn the instrument around the top screw until the pointer is deflected to the left of the graduated scale; then turn the milled head so as to bring the index up to the pointer, when the moving parts will be firmly clamped.

Lastly, the inside of the glass cover is coated with a layer of our transparent conducting varnish, described in the previous paper read to-night, and the instrument is thus screened from outside electrostatic action. Hence there is no fear of a change in the reading being produced by cleaning the glass—a very serious source of error, which is not uncommon with electromagnetic voltmeters in actual use in electric light central stations.

THE NORTHERN SOCIETY OF ELECTRICAL ENGINEERS.

We give below a report of the adjourned discussion on the paper read before this society by Mr. John H. Rider, entitled "Notes on Designing a System of Underground Electric Light Mains," and of the paper by Mr. S. V. Clirehugh on "The Various Systems of Underground Mains and Methods of Laying Same." The papers were given in our issue of March 16, and a report of the preliminary discussion in the *Electrical Engineer* of March 23.

Mr. Wooler: I myself should have liked to have heard some more definite advocacy of a particular system of mains and sound reasons given for such opinion, because it is patent that every class of mains have their advantages and disadvantages. For instance, bare copper conductors lay claim to economy in first cost. Well, this only applies where a large quantity of mains are required. One advantage which bare copper certainly does possess is the facility with which service connections can be made. What, however, I consider to be the most serious detriment to the use of bare copper is the space required to build the concrete culverts, and having to be frequently intersected with lengths of cables where headway cannot be obtained for the conduit, or underneath heavily-trafficked roadways where such a trench would not be calculated to sustain the weight unless strengthened to unwarrantable proportions, as demonstrated by Mr. Clirehugh with the samples on view. Mention has been made of fires and explosions. Well, in the very early stages of most new supply works it is their experience to have one or two disturbances of this kind. They answer the useful purpose of forcibly removing any weakness which may have been overlooked during construction, and generally benefit the undertaking by reason of preventive measures being taken for the future. In the case of cables under

* Tests made from month to month of the sensibility of two of the latest form of the Weston voltmeter show also that the sensibility slowly increases. This arises, probably, from the permanent magnets having been too much weakened before these instruments were originally calibrated, so that the magnets have increased their strength with time. These two instruments now read 1·3 per cent. and 1·7 per cent. too high respectively, after allowing for the fact that the unit P.D. employed in the original calibration was the legal volt, and not the "Board of Trade" or "International" volt.

Digitized by Google

the drawn-in system, all the injured ones would have to be pulled back to the next coupling-box on either side, renewed, jointed, and vulcanised, which would be a lengthy occupation, but if bare copper was concerned, the strip and porcelain insulators may be blackened, which, with cleaning, and a little adjustment, would soon be rectified. Both of the authors began their discourse asserting the importance of the question of mains bearing upon the designing of a central station; then they go on to tell you that bare copper conductors, although admissible for low tension, are unsuitable for high tension on account of induction effects: therefore choice is limited, and I contend that the primary feature is to decide upon the system to be adopted. If high tension is selected, then small mains with high insulation resistance, or concentric cables, as explained to you, will be required, and a preference for low tension means very heavy expenditure for thicker mains, in addition to the by no means ignorable item which becomes due for royalty upon finding yourselves compelled to distribute upon the three or five wire system to keep up the E.M.F. in congested quarters. Of course, with high tension, only a comparative fraction of copper could be wanted for conductors, but expenditure in the direction of transformers would absorb a portion of its equivalent in cost.

Mr. Corlett: There is one remark I should like to make about bare copper strip. Since the last meeting I have obtained some reliable figures as to results we get in actual practice, and I find at the station in Brighton, or rather in Hove, that in wet weather the average insulation resistance runs from ·35 to ·5 megohms per mile, and in dry weather we get from 2 to 3 megohms. I think this is a very satisfactory result. I find from figures I have had from Kensington station (the oldest three-wire system distributing on bare copper strip) the total cost for laying the system for Kensington amounted to £56,000. Of this amount upwards of £30,000 was spent in 1890, and nearly the whole of the remaining sum was spent in 1891. The following are the figures for maintenance, and included in this is all repairs to surface boxes caused by wearing away of cement, trifling modifications in pavement, resetting of boxes caused by reflagging, etc.: in 1888 the maintenance bill was £24; in 1889, £40; in 1890, £56; in 1891, £98; in 1892, £364; and in 1893, £280—making a total altogether of £862 for the six years. If we take it that the whole was spent in four years, or base our maintenance cost as this sum divided by four instead of by six, and take the capital outlay as £50,000, we get a sum of £215 a year in a capital outlay of £50,000, which works out ·43 per cent. per annum; and as local authorities can generally borrow money at 3½ per cent., the total cost to the town of the upkeep of these mains would only amount to 4 per cent.

Mr. T. Callender: Previous speakers seem to treat vulcanised rubber as the only material used for underground mains. This is hardly the fact, for when we look into details it is astonishing how little rubber actually is used and for distributing mains, especially to what an extent it is being superseded. I find that up to last Saturday there are 82 stations in the United Kingdom under the Electric Lighting Acts, which are either in actual work supplying electricity for lighting, or for whose mains definite contracts have been given out. These 82 stations have their mains insulated—39 exclusively by materials other than rubber; six are strip systems with bitumen cables; five have their network of cables other than rubber, but part of their high-pressure feeders are of rubber; 19 are rubber insulated throughout; seven are strip systems with rubber cables; and six are common to all, the cables being insulated by rubber and bitumen or of the lead-sheathed type. In lead-sheathed cables the mains for the 11 following stations were secured by Messrs. Siemens: Bradford, Kingston-on-Thames, Dewsbury, Bristol, Hampstead, Derby, Bolton, Halifax, Londonderry, part of St. Pancras, and Southport; whilst Salford, Exeter, Taunton, Yarmouth, and Harrogate are in the hands of other makers of lead-sheathed cables. The cables for Brighton, the Crystal Palace District, and for the City of London have been made partly by my company, partly by others. I now take the liberty of referring to the work of my company. In 15 stations the mains are laid by us throughout, part are with lead-sheathed cables, but the majority consist of vulcanised bitumen cables. The entire distribution networks have been laid by us at Oxford, Sheffield, Hanley, Coatbridge, and Huddersfield. We have laid our cables, in conjunction with more or less bare copper strip and culvert, at Pontypool, Northampton, Southampton, Aberdeen, Belfast, St. James's and Pall Mall District. Messrs. Johnson and Phillips are responsible for two stations—viz., Rochester and Keswick. Norwich and Preston are on bare strip systems of special designs. Having thus given a rough analysis of the mains actually in use or under construction, what inference may we draw? It certainly does not tend to show that rubber is the chief insulating material. Where it is in use it is almost entirely in connection with alternating-current work, and it appears to me that the future in this division of electrical distribution lies largely with lead-sheathed and armoured cables. The simplicity of laying has much to commend this type of main. I believe that the position which rubber still holds for high-pressure work is seriously menaced, especially for concentric cables, by the type of lead-sheathed cable now being made by Messrs. Siemens, my company, and other firms. I claim that among the systems which have come here to stay, which have been used in the past and will be in the future, are those identified with my company's name. In regard to bare strip, I agree with much Mr. Corlett has said. When the sections of conductor are heavy culvert and strip can be laid cheaper than cables, but heavy sections are required almost exclusively in busy streets, and such streets have an unfortunate knack of being encumbered with pipes and cellars. If you move these, the expense is so heavy that your saving in first cost vanishes, and the usual plan of putting in part strip and part cable is never quite satisfactory. Unlike most cable-makers, I have laid a good deal of culvert, and I know exactly its weak points. The only town with which I am acquainted thoroughly suitable for culverts is Dundee—the station here is on a hill and the lighting area close to the seaside; but unfortunately towns with such natural advantages for draining one's culverts are not often found, and I cannot consider strip and culvert as universally applicable or advantageous.

Mr. E. H. Nisbett: I should not have occupied the time of the meeting to-night but that I thought some account of our experiences in the City of London would be of interest to members. Mr. Rider does not seem to me to have made it quite clear whether in speaking of "feeders," he intended to include both high and low tension mains. If low-tension mains are referred to I am quite in accord with his suggestion that a "built in" system should be used for the distributors and a "draw in" system for the feeders, as in this case the cost of the conduits is a relatively small item, but for high-tension work the conduits may cost actually more than the cable itself. To illustrate what I mean, suppose we take the case of a feeder having ultimately to transmit, say, 200 kilowatts, and it is determined to put down for immediate requirements only one-third of the total quantity of copper. In the case of a three-wire low-tension distribution we might then have to at once put down one-third of one square inch of copper, say, 0·33 square inch; a triple concentric cable of this section would cost about £1,500 per mile, and a conduit to contain it, with two spare "ways," would cost £350 per mile, making an immediate outlay of £1,850 (neglecting trench work), and an ultimate expenditure of £4,850 per mile for the complete feeder. Against this an armoured cable of 0·33 square inch section would cost £1,600 per mile, showing a lower initial expenditure, but the ultimate cost would be £4,800, and £400 for second and third trenchings, making a total of £5,200 per mile, or more than the "draw in" system. Now in the case of high-tension work it is different. The same feeder working at 2,000 volts will be 0·1 square inch section. A cable of one-third of this section will cost £155 per mile, and the culvert to contain it £310, bringing the total immediate outlay to £465, and the ultimate outlay to £775 per mile. Now, for £465 per mile one can purchase an armoured cable of ·1 square inch section area, and so at once put down the whole of the copper estimated to be required. Mr. Rider mentions the distance apart of feeding points as being not more than 250 yards if the distributing mains are to be kept of a reasonable size. I think this is putting the feeding points very close together; conductors having a sectional area of 0·1 square inch will, if on three-wire system, provide for five 8-c.p. lamps per yard of frontage alight simultaneously with a drop of 1½ per cent. This, it appears to me, is a heavy demand for a provincial town. I may mention that in the City of London we have provided for a demand which averages out at 4·5 8-c.p. lamps per yard of frontage. I think it is a pity that Mr. Rider, after having so carefully pointed out the importance of avoiding self-induction for alternate-current work, should have gone back on that by adopting a type of cable in which the self-induction is quite appreciable. I have made some experiments in the City, from the results of which I am enabled to state that the impedance drop in the type and size of cable that Mr. Rider is using is about 10 per cent. over the ohmic drop at 200 volts and 125 amperes at 100 volts, and the loss in the lead and iron sheathing about 50 watts per mile—not a large amount perhaps, but certainly worth taking into consideration. I must take exception to Mr. Clirehugh's statement that indiarubber cables "stand at the top from a scientific point of view." What is the scientific point of view of a perfect cable? Is it great durability, great dielectric resistance to pressure, high insulation, easy jointing, and cheapness? If so, I do not think that indiarubber does stand at the top. Such a cable as that manufactured by the British Insulated Wire Company, and used by us for all our work in the City of London, at least on some of these points is far ahead of indiarubber. The rubber advocates object that there may be pinholes in the lead, but a hole is just as likely to occur in the rubber during manufacture, and much more likely to develop afterwards. I have here a sample of a cable which has been working only two years. When it was laid down in the City the indiarubber was apparently perfect; it has lately been examined, and several lengths have been found in which the rubber is very badly cracked and unfit for further use.

Mr. J. B. Atherton: I was only saying to-day, in talking over some matters of this kind, I think it a very great mistake that more was not said to elucidate the difficulties surrounding questions of this kind than seem to be the inclination. It would be much better if the meetings tended to bring out what was best rather than crying down what one another were doing.

Mr. L. Andrew: I should like to have the opportunity of saying, with reference to my statement at the last meeting, that vulcanised rubber cable had only been used for 10 or 12 years. I was referring to electric lighting cables. Neither of the papers had reference to telegraph and other kinds of cables.

Mr. G. E. Preece (vice-president): Having been personally alluded to at our last meeting, it was my intention to have offered some remarks at the present meeting, but being unfortunately confined to my room by the doctor's orders, I cannot be present, but I have written down some few observations with regard to the papers themselves and their subject-matter, which I trust may prove acceptable to the meeting. Roughly speaking, the ground covered by the two papers consist of two points: (1) the conduit; (2) the insulated cable or conductor. Amongst the various classes of conduit described, no mention was made of that form introduced by the International Subway Company, and lately entirely used

Digitized by Google

in Portsmouth for the town-lighting. It has also been used in other places, and largely in the United States. It figures up much cheaper than ordinary piping, and it has one very great advantage, that special facilities are provided for jointing and leading off from the mains to trenches or consumers' premises. As regards conduits for insulated conductors, the iron pipe and the drawing-in system has survived a usage of about 40 years, and is likely to last as long as it is necessary to place wires underground. One advantage of the iron-pipe system which has not been mentioned is that owing to the lengths of pipe used, and the excellence of the jointing, pipes do not give way owing to the inequality or subsidence of the ground, and the cables are not prevented from being drawn out, as has occurred in many of the built-up drawing-in systems. Lead piping has been frequently used, either pressed on hot, or pipes drawn down after the cable had been drawn in; but it has only been of late years that thorough attention has been paid to the internal insulation by a thorough dessication of the core before being soaked in the insulating material. There is no doubt but that in this form of cable we have now arrived at a very high pitch of perfection, and we are indebted to Mr. Clirehugh for an excellent description of the manufacture of paper insulation at the British Insulated Wire Company's works at Prescot, but I cannot help thinking that whilst such important improvements have been made with the core itself, no improvement has been made with the lead covering, which is practically the vital point in this form of cable. Indeed, I am inclined to think that from what I have seen and from information obtained, that the quality and durability of the lead used at the present time is not so good as that employed in the past. The question of maintenance and durability of this type of cable is essentially the question of the quality and durability of the lead and the excellence of its absolute perfect covering, for in that lies the strength and weakness of the cable as an insulated conductor, and, judging from my knowledge and experience of the material, and also by past experience, I am inclined to think that when it becomes a search for the "survival of the fittest," the lead-covered cable will not be there to answer. Since electric lighting has commenced vulcanised indiarubber has been used, and is being used at the present moment in increased quantities. Of its utility and especial adaptability to the work we have every proof, and of its durability every year gives additional evidence. There are cases where vulcanised rubber has not done good service, but this has been due to an inferior quality having been employed. As regards durability of vulcanised rubber, I show two samples of aerial cable sent us by Mr. Higgins, of the Exchange Telegraph Company. These were suspended in the air in November, 1873; they were taken down in 1893—20 years (nearly) after—on account of the house to which they were attached coming down, and not on account of any fault in the cables. The samples and letter are sufficiently explanatory. So far as efficiency and durability are concerned there can be no question but that vulcanised rubber has an excellent record, but some objections are made to it on account of its high insulation—unnecessarily high—and its expense. Some remarks have been made on the question of jointing vulcanised cores. There is really no difficulty about this, but for absolute perfection in a joint none but skilled workmen should be employed. I quite agree with Mr. Rider where he says in his paper, "I venture to think that a combined system of drawn-in for the feeders and built-in for the distributing mains offers a number of advantages." This plan was adopted with great success at Morecambe, and would be applicable to many cases. Gas explosions have been very frequent, but they are not so bad now as they used to be in the past, when the gas companies calculated on a loss of 25 per cent. through leakage at the joints of their pipes. At the present time the leakage in a good gas system is reduced to about 5 per cent. Gas is bound to get by filtration into electric pipes and conduits, and is sure to accumulate in the boxes. It is at this point ventilation should be adopted; a small pipe from the top of the box carried under the pavement and up the side of a house would prevent at once any gas from accumulating. Mr. Rider refers to telephone induction in his paper. The only way to efficiently prevent this on alternate-current working circuits is to employ no other form of cable but concentric, not only for mains, but for distribution.

Mr. Rider, in reply, said: I am sure that both Mr. Clirehugh and myself may feel satisfied that our papers have met with such useful discussion, though I am afraid that rubber held the day at our last meeting, and the points I raised hardly came in for discussion at all. My chief point was using "drawing-in" system for feeders and armoured system for distributors. Mr. Mountain and several others agree with that. Mr. Nisbett does not, and points out that an armoured feeder can be put down more cheaply. The Board of Trade have limited us to 100 h.p. for our transforming centres with the result that a cable for 200 kilowatts is out of the question, and as I should only put down a feeder for one feeding centre the advantage of an armoured system is not so apparent. My great point is "drawn-in" system for feeders. Where you have to go to distant districts you have to put an entirely new feeder down, and that feeder has often to go through the district already lighted. Bristol had just started when an outlying district wished to be supplied, and there was a terrible hubbub because they could not tap on to their present mains. There was a fine row about it, and electric lighting cannot afford to make any subject for heavy discussion in that way. You want to do it so that shopkeepers are not put to any inconvenience. If you have the pavement up in front of a main shop several times the shopkeeper will look at you in anything but a friendly spirit. Mr. Mountain spoke of splitting up a network instead of jointing the whole into one large network. In big towns, if a fault occurs on the other side of a town in the same network the whole system is jeopardised. In splitting up your network you there have the advantage of a breakdown in one part not affecting any other. Mr. Mountain says, with reference to the cables we are adopting in Bolton, that he did not know how three cables would be distinguished. I have a sample here, from which you will see that the distinguishing is very easy. We have three wires coming together in one sheath, the middle cable is lapped with jute strand, the other with jute strand and one string, and the other (the third) with a number of strings laid on over the jute the other way, so that on opening the cables you have no trouble in distinguishing. Mr. Mountain further spoke with regard to what he thought was a hollow in the centre. From the sample you will see that there is no hollow, and therefore no chance of moisture coming in. With regard to Mr. Clirehugh's table, he gives the cost of excavations at 5s. per yard. Mr. Cowan said it could be done for 1s. 2d. I can corroborate that. In Bolton we can supply and lay a 3in. pipe at 2s. 9d., and putting down 1s. 8d., the cost of pipe leaves only 1s. 1d. for the excavations, and at that the gas department can make a profit. I am sorry Mr. Clirehugh dismissed the armoured systems in one paragraph. I think there is a great future for them. I was also sorry that Mr. Clirehugh did not mention Callender's solid bitumen system, as that is one that should have a great future before it, at any rate for direct-current work. Lead-covered cables are all right if the lead is put properly on, and you should go to a maker who will put it on properly, so that there is no dross in it. If it is properly put on cold you have it without fear of pinholes. Mr. Clirehugh does not agree with me in regard to "drawn-in" feeders. Mr. Bourne and Mr. Nisbett both refer to the possibility of a drop owing to the three cables not being exactly central. To get rid of induction entirely, the three wires must be exactly central. I do not think that Mr. Nisbett can have tried a cable as we are going to use it, as none have been made. I agree with the speakers as to Crompton's bare copper. If you use proper insulators you can get rid of leakage, but if you put on saddle pieces you are bound to get leakage. It is not a point at all looked after as it ought to be in bare copper systems. They cannot be adulterated. The manufacturer cannot put into them any oxide of zinc, size, or rubber substitute. But with rubber cables he never knows within 20 per cent. how much adulterant it contains. I am sorry that Mr. Clirehugh withdrew his remarks about the difficulty of vulcanising joints. There is undoubtedly great difficulty in securing a good joint by this method, so much so that I may mention that some time ago we bought a considerable quantity of indiarubber-covered cable from a well-known manufacturer, but our men were quite unable to make good joints with the jointing material sent with the cable, and we were therefore obliged to purchase elsewhere. As regards flexibility, we lately tested a piece of 0·3 square inch triple concentric paper cable of 1½in. diameter, bending it to a 30in. radius and straightening it again without damaging it. It then successfully withstood a pressure of 4,500 volts, although only designed to work at 200 volts. A piece of rubber cable sold to the City Company for low-tension work broke down under the same pressure. Mr. Clirehugh states that under certain circumstances it is possible to draw 80 to 100 yards of cable in one length. In the City we have drawn as much as 185 yards of cable at one time, the length weighing two tons. Mr. Mountain at the last meeting said that paper-insulated cables were not suitable for high-tension work. Now, if they are suitable for anything at all, they are certainly suitable for use with high pressures. Mr. Wilkinson is now putting down paper cable at Southport, and he has lately been testing them to 20,000 volts without any sign of a breakdown—the thickness of the dielectric being only $\frac{1}{10}$in. The cables supplied to us in the City of London, and having to work at 2,000 volts, are tested after being laid and jointed to 10,000 volts.

Mr. S. V. Clirehugh, in reply, said: The main feature has been the discussion as to the difficulty of vulcanising joints in indiarubber cables, and there has been a certain amount of disagreement on the subject even among manufacturers of rubber cables. They have all stated that the difficulties of vulcanising have been over-rated, but it is admitted that it is desirable, nay, necessary, to send the jointers to the manufacturers to be taught to vulcanise properly, with the result that these men upon whom you have no hold are taught a trade at your expense, and afterwards, of course, demand very high wages. I believe the London supply companies are paying vulcanisers 10d. and 1s. per hour, and they are difficult to procure at that. Mr. Mountain has stated that he considers fibrous cable may be good for low tension, but hardly for high. He is, I think, under some misapprehension here, as fibrous cables have been used very extensively for the highest known pressures, and have only comparatively recently come into use for low tension. Plain lead-covered cables should certainly not be laid direct in the ground, but should be either drawn into iron pipes or protected by armour. With regard to Mr. Bourne's remarks, no doubt it would be possible to get sufficient insulation resistance with a less radial thickness of paper. It is, however, increased in order to get the mechanical strength required. With reference to Mr. Cowan's remarks *re* the cost of laying 3in. cast-iron piping, I had intended to convey the information that the price of 5s. per yard included the cost of the pipes, opening the ground and making good, temporarily, drawing in the cables, and including the Vestry charges; also joint boxes at the rate of 12 per mile. There was, however, a mistake in the table which I had not noticed. Mr. Nisbett says that I have damned lead-covered cables with faint praise, and he seems to be under the impression that my paper was intended to advocate the sole use of lead-covered cables. This was by no means the case, as, though I have great faith in them, they have not yet taken the place of rubber.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" *can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—*

	3 months	6 months	12 month
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements should be made payable to C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."*

COMPANIES' REPORTS.

The period has almost arrived when the real position of electric lighting enterprises can be ascertained. There ought to be a large audience next Thursday at the meeting of the Institution to hear Mr. Crompton's paper on the "Cost of Electrical Energy." We have always agreed with those members who desire to obtain a copy of an interesting paper, say, a day before the reading, so that they may be in a position to adequately discuss it. Perhaps we might venture to suggest the sending of a post-card to the ever courteous secretary by those who desire to thus see a copy in advance, and, no doubt, when papers are received in good time, and are in type, the Council would permit the sending of copies to possible debaters. As it is, a few men, more or less intimately connected with the Council or the author, have an advantage: and it may be due to this that the discussions are too often restricted to men around the table. It is almost impossible to keep from general statements when speaking to a paper only heard rapidly read, or read in abstract. The value of discussion is not in the generalities, but in the specialities, and the closer a speaker keeps to the text of the paper the more valuable his speech. Of course we cannot comment upon a paper unread, nor have we any desire so to do, but the publication elsewhere in our columns of two reports—one from a large company, the other from a local authority—raises questions which may or may not be discussed by Mr. Crompton. For example, sufficient money has been spent on central stations for an analysis to be made so as to compare the cost per unit which a supply company pays with that which a local authority pays. Another analysis much required is the annual percentage, so to speak, of capital taken up in progression. Let us explain what we mean. A very large amount of initial outlay—that is, capital expenditure—as we all know, is usually laid down in mains as a preparation for extension. Suppose, now, someone with a little time to spare, and who had the information which, unfortunately, journalists cannot well get, would calculate the capital expenditure required for mains for the distribution at the end of, say, three months' working. Take that as the necessary expenditure. During the succeeding twelve months a certain number of lamps are added, and the supply of energy is increased. This increase would account for another part of the capital expenditure in mains. Gradually, the full load that the mains will carry is obtained. We think that a careful analysis of different stations would show how fast or how slowly the initial capital is absorbed in productive capital. If this could be done, and the result was, as we fancy it would be, satisfactory, many more local authorities would be in favour of immediate action rather than of delay. Take the Metropolitan report. It shows a capital expenditure of practically £600,000, and this brings in a gross return of £69,000, or a net return of close on £16,000. The shareholders are to get five shillings per £10 share. The promises of the chairman of this company have hardly been fulfilled. What, however, we want

Digitized by Google

to know is the amount of capital which is really earning this £16,000, and the amount of what we call unproductive capital. This in many cases will also enable us to tell another tale. Capital may have been wasted, and in some cases, no matter how soon full load is obtained, the earning power of that part of the capital utilised productively will be insufficient to pay a dividend on itself and that part wasted. If we were much interested in the Metropolitan as shareholders, we should want to know a little more about some of the items charged to capital. We think the balance-sheet sails very closely to the illegal line, that various items are placed to capital account which ought not to be there. The accounts of the St. Pancras Vestry will be closely examined by all local authorities, and here is shown a net revenue of £6,200 obtained with a capital expenditure of £100,000. Comparing this with the Metropolitan, the St. Pancras Vestry would show at the above rate a net return of £37,400, instead of the £16,000 shown in the other accounts. The comparison, if we cared to continue it, would be immensely more in favour of St. Pancras than the Metropolitan—but such comparisons are odious because the data are doubtful. We know not how much of the Metropolitan expenditure is as yet unproductive. It may be that the St. Pancras expenditure is all productive, and the other mostly unproductive. But these things want closely watching.

WINDY.

Last week we made use of the fact that a meeting of the Tramways Institute was then being held in Manchester as a peg whereon to hold a brief dissertation upon tramway matters in general, and the prospects or possibilities of the overhead conductor or trolley-wire system in particular. The publication elsewhere in this issue of a paper brought before the institute at this meeting—viz., that contributed by M. Victor Popp, of Paris, under the title of "Mechanical Tramway Traction: Compressed Air or Electricity"—gives a further opportunity for criticism not only upon the paper itself and the views expressed therein, but also with reference to the institute, and its true scope.

It is certainly a fact that they manage some things at least better in France than here, and the quality of work done by the author of the above paper in erecting power distribution systems throughout certain parts of Paris has doubtless been such as might with advantage find imitators on this side of the Channel. It is, however, becoming a serious question with us whether the countrymen of Jules Verne do not regard as substantial facts the fantastic results of this great novelist's imagination. Certainly, we cannot otherwise very easily explain the large number of extraordinary French engineering enterprises lately "seen in the flesh"—solid, tangible facts, such as the Heilmann locomotive, the electric locomotives said to be in process of manufacture by the Paris, Lyons, and Mediterranean Railway Company, and designed to run the main-line expresses by means of accumulators, and, lastly, the compressed-air tramcar system advocated by M. Popp, examples of which (in its unregenerate form) are to be seen in the neighbourhood of Paris.

In our ignorance and insular prejudice we had somehow got the idea that compressed air—as a motive power even upon tramways, where light loads are the rule—was, to put it mildly, "played out" some time ago. The difficulties involved in combating the variations of temperature which follow upon the compression and expansion of air have been practically insuperable, so long as the element of economy remains the most important consideration. Then, again, the questions of storage, the weight and size of suitable reservoirs, are matters not settled quite so easily or satisfactorily as might be thought possible. All these disadvantages are, we must confess, frankly acknowledged by M. Popp, who claims, however, that they are largely, if not wholly, avoided by the newer forms and appliances which he advocates for the use of compressed air on tramways.

It is not our main object here to point out the objections which might be raised to the employment of this system; it has many advantages of an important character. Each car is self-contained, and no obstruction is created in or on the streets and roads. The sole test or standard by which compressed air may be compared with electricity as a suitable motive power for tramways is the question of expense—first cost and daily outgoing. Until more details are given, of a reliable nature, than are set forth in M. Popp's paper, we cannot very well attempt any decision of this point, or examination into the problem generally. We do, however, wish to protest very strongly against the assumptions and statements made by M. Popp in drawing up his indictment of electric traction.

Everyone, of course, is fully aware of the objections to the use of electric accumulator cars—perhaps none more so than those who have been unfortunate enough to try them in actual service. This type of electric working stands pretty much on a level with compressed air itself: though we feel somewhat generous in admitting this, taking, for instance, the figures given by M. Popp with regard to the weight of cars. An accumulator car weighing, without passengers, seven and a half tons might have existed years ago, but we have progressed a little further than that now, though so long as lead remains the metallic base of accumulators the weight will always be prohibitive. It is when M. Popp attempts to criticise the overhead conductor system that he fails most miserably; indeed, it is hardly possible to take his arguments seriously. The best proof of their value lies in the fact that Germany, Italy, and even France are all erecting overhead wires for the operation of tramways in some of the principal streets in the principal towns and cities; and M. Popp's naïve confession that the trolley system is used in America "for want of a better," puts the whole question in a nutshell. There is no better, taking it all round; and hence its increasing adoption. The wires, M. Popp says, are in the way of fire-escapes and festival cars! Let the fire-escapes be turned into horizontal built-up fire-ladders on wheels,

Digitized by Google

that can be whipped round by horses to a fire in half the time that an unwieldy perpendicular staircase takes for two or three men to push along. As for the festival cars, they will have to take trips into the country outside the towns: to claim that they shall interfere with the everyday efficient and economical working of tramways can only be characterised as absurd.

Whilst criticism of this kind is made necessary, a tribute of praise may well be given to M. Popp and those who have collaborated with him in perfecting the details of this ingenious system which the paper describes and advocate. We do not think for a moment that it will ever come into extensive use, but that does not prevent appreciation of its development as herein set forth. The Tramways Institute, moreover, will serve a most useful purpose if it obtains other papers from well-known engineers for perusal at the quarterly meetings; up to a little while ago the quality of communications brought forward was not, perhaps, of such high quality as the potential importance of this institute would appear to demand, but we are glad to note a steady improvement for some time past: and if the officials of the institute will only remember how great a field lies before them on the growing introduction of mechanical powers upon our tramways, they can raise the position and prospects of the institute very materially. The papers to be read should come from engineers and officials in the front rank in order to gain the attention of the world at large, and they should be reserved for the institute, and not consist merely of rehashed articles from the technical Press. With these points in mind, and a continuation of the same energy that now characterises the institute, there should be a prosperous and important future for this organisation, whether its members are connected with lines owned and operated by companies or by municipalities.

THE ELECTRICAL STUDENT'S A B C.

A is the Amp. that went into the Arc.
B is the Brush, sometimes seen with a spark.
C is the Copper, most handy for mains.
D is the Dynamo driven without reins.
E is the Science we study and pass in.
F is the Field, with more iron than grass in.
G is the Galvo., which "shorts" can foretell.
H Hysteresis, heats iron like —— (anything).
I is Induction, much blessed and cursed, too.
J is the Joule, set in carbon and cu.
K is the Kathode, who lives in a bath.
L is the Line cut by wires in its path.
M is the motor, which torques as it works.
N Non-conductor, which carrying shirks.
O is the Ohm found in wire as in brick.
P is the Pole which to iron wood stick.
Q the Quickbreak on a high-voltage circ.
R the Rheostat, which 'eats when at work.
S is the Switch, like the ones used with trams.
T is the Telephone; earns many bad —— (words).
U is the Unit, at fourpence a blessing.
V is the Volt, who is always most pressing.
W the Watt; E.C., when you know it.
X the Xpense. House installers should blow it.
Y is the Yoke, which in magnets is grey.
And the
Z inc has connection with bells every day.

April, 12, 1894. J. H. C. B.

ON CERTAIN NEW PREFIXES PROPOSED FOR PHYSICAL UNIT MAGNITUDES.

BY EDWIN J. HOUSTON, PH.D., AND A. E. KENNELLY, F.R.A.S.

The increasing extent to which scientific unit magnitudes are being used in physical research has received a check by the inconvenient size of some of the fundamental C.G.S. units, particularly the dyne and the erg.

In order to lessen this inconvenience, we would propose the following additional prefixes, which we have found convenient in our own work.

For example, instead of writing "one thousand megergs" we would suggest the term "one begerg"; and, similarly, for the expression "one million megergs" the term "tregerg," and for a "billion megergs" a "quegerg," following the analogy presented by the words million, billion, trillion, and quadrillion.

Again, instead of writing "the one thousandth of a microfarad," we would suggest the use of the term "bicrofarad," and also the tricofarad as the millionth of a microfarad where necessary. The meaning of these suggested prefixes is, therefore, as follows:

Bega = 1,000 million, or a billion, or 10^9.
Trega = one million million, or a trillion, or 10^{12}.
Quega = 1,000 trillion, or a quadrillion, or 10^{15}.
Bicro = 1,000 millionth, or 10^{-9}.
Tricro = one trillionth, or 10^{-12}.

The following applications of these prefixes will suggest their advantages.

From 1 metre = 1· metre = 100· cms.,
and 1 mm. = 0·001 metre = 0·1 cm.,
and 1 micro-metre = 1· micron = 0·000,001 metre = 10^{-6} metre = 10^{-4} cm.,
1 bicro-metre = 1 bicron = 0·000,000,001 metre = 10^{-9} metre = 10^{-7} cm.,
1 tricro-metre = 1 tricron = 0·000,000,000,001 metre = 10^{-12} metre = 10^{-10} cm.

The micron is of the order of the length of a light wave in the ether, and is a fundamental unit of magnitude in microscopy.

The bicron is a magnitude which will be useful in dealing with the mean free path of gaseous molecules, according to the kinetic theory of gases.

The tricron is of the order of molecular dimensions, according to the estimate of Kelvin.

From 1 megadyne = 10^6 dynes = approximately the earth's gravitational force on one kilogramme of matter.

One begadyne = 10^9 dynes = roughly the earth's force on one ton of matter—*i.e.*, the weight of one ton.

One tregadyne = 10^{12} dynes = roughly the weight of 1,000 tons.

1 megarg = 10^6 ergs = 0·0737 foot-pound at Greenwich.
1 begerg = 10^9 ergs = 73·7 foot-pounds at Greenwich.
1 tregerg = 10^{12} ergs = 73,730 foot-pounds at Greenwich = 37 foot-tons approximately.

From 1 megohm = 10^6 ohms.
1 begohm = 10^9 ohms = 1,000 megohms.
1 tregohm = 10^{12} ohms = 1,000,000 megohms.
1 quegohm = 10^{15} ohms = 1,000 tregohms.

A begohm is about the insulation of one mile of well-insulated conductor.

A tregohm is about the resistance required to limit the deflection of a high-grade mirror galvanometer under one volt to one scale division of one millimetre at one metre range. Such a galvanometer might be called a tregohm galvanometer.

A quegohm is the limiting resistance with one volt and unit deflection of an extremely sensitive mirror galvanometer, which might be termed a quegohm galvanometer.

From 1 microfarad = 10^{-6} farad.
1 bicrofarad = 10^{-9} farad, or 1/1,000 microfarad.

The C.G.S. electromagnetic unity of capacity being 10^9 farads is consequently a begafarad. The use of these prefixes, therefore, assigns a convenient name to the C.G.S. unit of capacity, which would otherwise require a special denomination.

From 1 henry = 10^9 cms.
and 1 microhenry = 10^3 cms.
1 bicrohenry = 1 cm.

CONTINUOUS-CURRENT TRANSFORMERS IN SUB-STATIONS.*

Several alterations are being made by the Paris Compressed Air Company in the sub-stations which they established for the supply of electrical energy in the district over which the company have powers. Among these is the use of continuous-current transformers in place of certain sets of batteries which have hitherto been used for the total service. The primary circuit of this transformer, connected in circuit with the primaries of the other stations, receives electrical energy at high tension from the Saint-Fargeau station or from that in the Boulevard Richard Lenoir. It works as a motor, and actuates a generating dynamo giving current at 120 volts. The same arrangements have been adopted in all the sub-stations, of which there are 23 in Paris. We will now proceed to refer to the sub-station in the Bazar of the Hotel de Ville.

This sub-station contains two batteries of 67 accumulators, of the type made by the Société pour le Travail Electrique des Metaux, of a capacity of 2,500 ampere-hours, and two continuous-current transformers. The accumulators serve to keep the pressure constant, and to replace the transformers in case of necessity. The transformers are respectively of 70 kilowatts and 33 kilowatts capacity; they are formed of two Thury dynamos having six forged-iron inductor poles, and are coupled together by a Raffard coupling. A switchboard is provided for each dynamo. The motor is excited in series and the generating dynamo in shunt. The current in the primary circuit of the 33-kilowatt transformer can reach 275 amperes at 175 volts, and 300 amperes at 110 to 120 volts at a speed of 550 revolutions. The figures for the 70-kilowatt transformer are 340 volts and 275 amperes in the primary circuit, and 110 to 120 volts and 640 amperes in the secondary circuit at a speed of 450 revolutions.

Our illustrations, Figs. 1 and 2, show the arrangements of the distributing switchboards. At P and P', Fig. 1, is shown the two wires of the high-tension circuit. The current passes through an ammeter, A, a switch, C, the armature, H, of the motor, M, and the inductor, I; a portion passes along the cable, X, into a graduating rheostat, R. The circuit is afterwards closed by a switch, C^1, which is connected to the leading-out wire, P'. Several other appliances are placed in shunt. V is an automatic safety appliance, which normally should be open; when an accident takes place, or when the difference of potential rises above the normal, a fine wire solenoid attracts a soft-iron lever, which short-circuits the line. B is a voltmeter with a fusible cut-out, E; and D is a switch which allows of the sub-station being short-circuited at the moment of stoppage.

The low-tension switchboard, Fig. 2, carries an ammeter, A, a voltmeter, B, an automatic switch, C, a switch, D, and fusible cut-outs, E and E^1. A hand rheostat, R, permits of the resistance of the excitation in shunt being varied at will. A third and general switchboard allows of the station being short-circuited in case of accident, or of successively isolating each of the transformers, or of substituting equivalent resistances for them.

The various operations in a sub station of this kind are as follow: (1) the starting of the transformers for a large demand by utilising, in case of necessity, the discharge of the accumulators to make up the total power to be distributed; (2) the stoppage of the transformers after the greatest demand; (3) the charging of a part of the accumulators and the discharging of the other portion of the cells.

To set the transformer in operation the safety appliance, V (Fig. 1), is opened, the switches, C and C^1, are put in the contact-pieces, and the rheostat, R, is at the bottom of the course, at Z—that is to say, out of circuit. The switch, D, is then opened. The general circuit of the motor is found to be closed, and the current passes through the ammeter, A, the plug C, the armature, H, and the cable, X. By varying the resistance, R, the motor, M, starts, and it is only necessary to regulate this resistance to impart the desired speed to the generator, G, as shown in Fig. 2. When the difference of potential has reached the normal the automatic switch is closed and the resistance, R, is regulated.

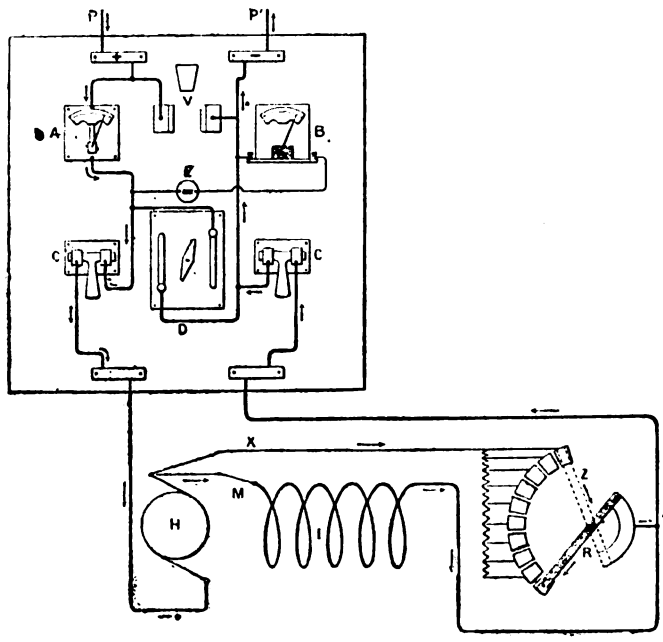

FIG. 1.

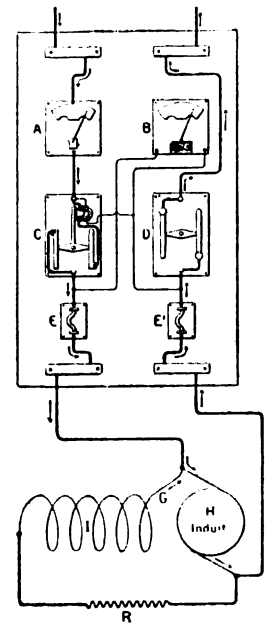

FIG. 2.

If at a given moment the power expended in the external circuit becomes greater than that produced by the transformer, one or two batteries are connected in quantity with the latter.

The stoppage of the transformer is commenced by diminishing the resistance, R (Fig. 1), of the motor, so as to reduce the speed of the latter. When the difference of potential falls to 0 on the distributing switchboard, Fig. 2, the switch, D, is opened, the switch, D, on the first switchboard is closed, and the switches C and C^1 are pulled back.

Each of the transformers is provided with automatic rheostats, with centrifugal force regulators allowing of the secondary difference of potential being maintained constant. It is claimed that the efficiency of the transformers at full load is 80 per cent.

* Abstracted from *L'Industrie Electrique*.

Hungary.—The town of Erlau is to be included in the telephonic system connecting Budapest and other Hungarian towns if a sufficient number of subscribers comes forward.

A 5,000-H.P. WATER-POWER PLANT.

Considerable interest is being manifested in the United States in the new water-power plant of the Concord Land and Water Power Company at Sewall's Falls, on the Merrimack River, about three miles above Concord, N.H. It is believed, with the exception of the Niagara Falls power station in course of construction, that this is the largest water-power plant in existence that is in practical operation. The water was turned on and the plant started at the end of February.

Mr. A. C. Shaw, who describes the generating station and plant in the *Electrical Engineer* of New York, states that the first problem to be solved was the damming of the Merrimack River, and that the services of one of the best hydraulic engineers in the country were brought into requisition—the design for the dam being furnished by Mr. E. F. Smith, of Philadelphia, engineer and superintendent of Schuylkill and Tide Water Canal, and the details of construction carefully carried out by Mr. Daniel Ulrich, of Newark, N.J. The dam is of the crib construction filled in with broken stone, is 497ft. long, 67½ft. wide, and is 22ft. deep from the comb to the bottom of the foundations. The fall of the water from the comb of the dam to the bed of the river below is 14ft., and is gradual, the water being allowed to flow over three or four easy drops and slopes and pass away comparatively quietly on to the bed of the river. The canal is 1,300ft. long, 60ft. wide at the surface and 10ft. wide at the bottom, with an average depth of about 11ft. There are five openings, each provided with a gate 10ft. by 10ft., and the three centre gates are each fitted with an auxiliary gate 5ft. by 2ft. as it would be impossible to open the large gates when there is any considerable difference of level between the river and the canal. The canal runs the whole length of the power-house, its foundation wall forming one side, in which are set the immense penstocks which convey the water from the canal to the wheel cases. At the end of the canal, with one end tied into the power-house, is the waste-weir, fitted with removable flashboard, so that any level of water can be preserved in the canal.

The power-house, which has been designed for 2,000 h.p., is of substantial mill construction without any ornamentation, is 160ft. long, 45ft. wide, and 47ft. high from the foundation to the top of the roof. The foundation is composed of 10in. by 10in. ties, puddled into a hard pan bottom, with sheet piling at the sides. On top of the timbers is a layer of plank upon which rests the masonry. There are three longitudinal walls of masonry of separate heights and depths, tied together at every pulley pit. The canal wall, which is naturally not so deep as the others, owing to the difference in level of the canal and the tail race, is 6ft. 4in. wide at the bottom, has the front face vertical, is 2ft. 10in. thick at the top, and is 22½ft. high. The other two walls are 5ft. thick at the bottom, 3ft. at the top, and 26½ft. high. The canal wall is 6ft. 9in. higher than the other two walls, to protect the generator-room from possible inundation in time of flood. These walls are of solid granite and cement, and on them rests the brick walls of the generator-room, which are 20in. thick, and built with solid lime cement.

The wheel-room is 150ft. long by 15ft. 10in. wide and 15ft. high, and is designed to accommodate five pairs of 39in. horizontal turbines, four of which are now in position, of the Rodney Hunt type, manufactured specially for this work by the Rodney Hunt Machine Company, of Orange, Mass. Each pair of wheels is contained in a case 8½ft. in diameter by 11ft. long, and will develop 400 h.p., each wheel being designed for 200 h.p. Each case is connected to the canal by one 8½ft. ⅜in. steel penstock, passing through the centre wall, and ending with a cast-iron flange on the outside face of the canal wall, in the forebay. The water leaves the wheel case through a 48in. steel quarter turn, and passes through a steel draught tube 48in. in diameter, set at an angle of 40deg. from the vertical, and passes out horizontally into the tail race, the bottom end of the tube being bent for this purpose.

These tubes are at all times full of water, the water backing clear to the wheels, thus getting the full power of the entire fall without having the wheel submerged at the lowest depth, and enabling belt transmission to be used instead of the ordinary noisy gearing and shafting. The shaft, 6½in. in diameter and 29ft. long, extends through both wheels and both quarter turns, and is connected at one end by means of a coupling to the transmitter pulley, which is a heavy cast-iron flywheel, 11ft. 6in. diameter by 32in. face, revolving at 150 revolutions per minute. Each shaft is entirely separate from the others, making separate units, and each unit can be used separately, or combined by means of friction couplings on the floor above.

Each pulley runs in a boiler-plate, watertight belt-pan, which extends to the centre of the shaft, so that even should the wheel-room become flooded, there would be no damage to the belts, unless the water should rise higher than the shafting, a contingency extremely improbable, as ample pump capacity is provided to take care of any water leaking or percolating into the wheel-room. The power is transmitted by 32in. double oak-tanned waterproof belts.

The generator-room, which contains the generators and the shafting, is 150ft. long by 40ft. wide, and 15ft. high. The shafting, which makes 300 revolutions per minute, is of hammered iron, and is 5in. in diameter, set in solid masonry foundations, and equipped throughout with ring oiling bearings. The main receiving pulleys are 5ft. 9in. in diameter by 32in. face, and are supported on a quill, with special quill bearings, so that the waterwheels can be started up independently of the shafting. The pulleys are fastened to the shaft with taper sleeve arrangement, which obviates all necessity for key ways and set screws, and makes the shaft much more rigid. The rims of the large pulleys are 2in. thick, and the whole shafting, in fact, has been made extra heavy, forming in effect one large fly-wheel, the inertia of which is an important factor in the regulation of the plant. This device has never before been employed, and is original with Mr. Carpenter. Hill friction clutches are used throughout, by means of which any combination can be secured, the wheel at the one end of the power-house being capable of being used to trasmit power to a generator at the other end of the power-house if so desired. The generator-room contains at present seven Thomson-Houston 50-light arc light dynamos, and six 250-kilowatt triphase generators, the second plant to use the triphase current in the United States. These generators will furnish current for incandescent lights, power, heating, and cooking, all of which is at present being done from the company's circuits. The voltage of these triphase generators is 2,500, and the voltage at centre of distribution in Concord 2,200, where it is transformed to 110 volts, at which pressure it is used for the purposes enumerated above. The company is now operating about 5,000 incandescent lights, 250 arc lights, and 400 h.p. in motors. The electric apparatus has been manufactured by the General Electric Company, the generators and motors having been designed by Dr. Louis Bell.

MECHANICAL TRAMWAY TRACTION: COMPRESSED AIR OR ELECTRICITY.*

BY M. VICTOR POPP.

Electric Propulsion.

When an electric accumulator puts forth the energy that has been stored in it, this energy is already going through its fifth transformation—viz. :

1. Transformation of the initial heat into motive power. Transforming medium : the steam-engine.
2. Transformation of motive power into electricity. Transforming medium : the dynamo.
3. Transformation of electricity into chemical electrolytic work. Transforming medium : the electric accumulator during the charging process.
4. Transformation of the chemical electrolytic work into electricity. Transforming medium : the electric accumulator while discharging.
5. Transformation of this second generation of electricity into motive power, as in the case of an electric tramway. Transforming medium : the electric motor.

When the accumulator is used for lighting purposes, the chemical electrolytic work is transformed into heat and light by means of the outgoing currents. In this case, the lamps are the transforming medium. Should the accumulator be used for the electrolysis, the chemical electrolytic work is converted by the same

* Paper read before the meeting of the Tramways Institute at Manchester.

intermediary into other work of the same kind. And, as a loss of energy is fatally consequent upon each transformation, we easily perceive what the final return must be in comparison with the expense of initial energy. This return is undoubtedly inferior to any obtained by other processes of mechanical propulsion for the same cost of initial energy. Experience and theory agree in this. The great dead-weight which a battery of accumulators of sufficient power and capacity adds to a car, the waste of time in recharging, the cost of renewing and forming plates, are so many inconveniences which it has been sought to avoid by the use of elevated or underground conductors along the entire length of line. In fact, propulsion by means of accumulators is incontestably much the most expensive of all methods. Low efficiency, extravagant cost of maintenance and renewal, are such acknowledged deficiencies as to put it beyond question that this method of mechanical traction can show at best but a trifling economy over animal traction. Consequently it is but little used. The Tramways Company and the General Omnibus Company of Paris, after careful investigation, have definitely refused to consider the use of accumulators.

Electric tramways, not on the accumulator system, are worked by means of elevated or underground conductors. Current is supplied to the cars by grooved wheels or brushes running along these conductors. The return of the current is generally effected through the rails. The successive transformations of initial energy are, in this case, only three, but to the losses occasioned by these transformations must be added those resulting from the resistance of the line and the imperfect insulation. We have also to consider the considerable cost of erecting the conductor, the metal itself, the poles, insulators, etc. It is true that these expenses are incurred only at installation, but the cost of maintenance of both elevated and underground systems are great, especially in the latter case. As the principal drawback to electric traction by overhead conductors lies in the cost of maintenance, we will give some details on that point. The wire carrying the current is always suspended above the middle of the track on which the cars run. Usually current is transmitted by a single wire suspended above each track, and the circuit is completed by the rails. In some cases, where owing to some special conditions of track the return of the current cannot advantageously be effected through the rails, a complete suspended circuit is established which requires two wires for each track, one transmitting the current to the motors and the other returning it to the central station. Experience shows the difficulty of establishing and maintaining connection with the conductor at the curves and switches. The poles, brackets, and interlacing wires are encumbrances and unsightly. Municipalities which regard the appearance of their streets refuse to allow their installation. These elevated wires, with their poles and other supports, are so great a nuisance and so unsightly that we are not astonished at their proscription from the thoroughfares of most European cities. For that very reason the capital of Austria has definitely rejected all systems of mechanical propulsion making use of elevated conductors At Brussels, where electric tramway lines with elevated conductors are now being established, very serious complaints have already been laid before the Town Council by the heads of the fire department, these wires being in the way of the fire ladders. The committee of the Brussels fêtes has protested against the establishment of these wires on account of interfering with the festival cars. Owing to similar complaints the Electric Tramways Company of Marseilles has been forced at a great cost to raise its wires and to change their position at certain points. In France, the Minister for Commerce and Industry has presented a Bill regulating the conditions under which electric conductors for transmission of power shall be established. The constant increase of electric installations for distribution of light or motive power, the dangers they present to the public safety, the disturbance they may occasion in the telegraph and telephone lines in their vicinity, cannot fail to attract the attention of the authorities. In future, permission to establish conductors on public thoroughfares, or in their immediate vicinity, will be limited by Government to such an extent as will ensure public safety and protection of the telegraph and telephone service. Every application made to public authorities for the establishment of electric conductors in France will have to be submitted to the consideration of the Government engineers before any concession is granted.

If in America the trolley system is in use it is only for want of a better. We hear that one of the most important tramway companies of New York is offering a prize of 50,000dol. to the lucky inventor who shall discover a better system of propulsion. In the meantime this company is establishing cable lines in preference to trolley wires. The high tension of the currents generally used for traction not only interferes with telegraph and telephone, but presents also a serious danger to public safety, as has been stated in the Bill proposed by the French Government. Recently, during a fire at Boston, where the elevated wires are so numerous and so entangled as to cover some streets with a metallic network, the firemen were not only prevented by wires from using their ladders, but a number of them received heavy shocks. For the twentieth time, at least, the insurance companies have demanded that all wires be buried.

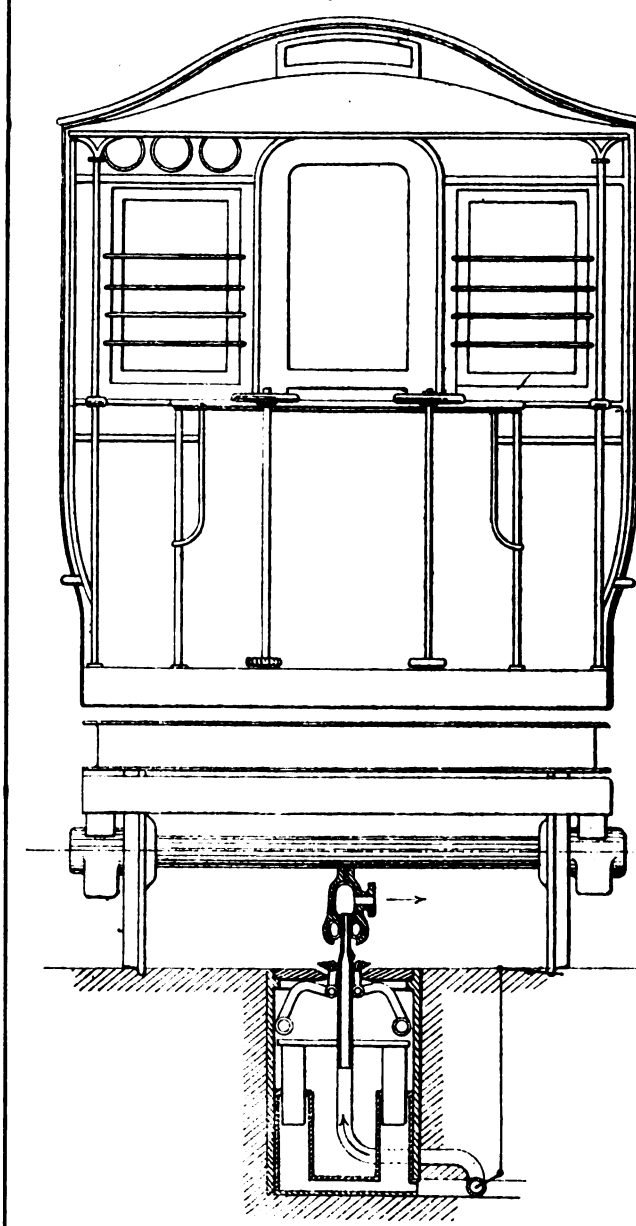
At first sight one might think electric propulsion by means of underground conductors preferable to the elevated system, but the trials already made show that, aside from the disturbances occasioned among other electric services, their establishment and maintenance costs a great deal more than the elevated wire or compressed air systems. That is why this system has been little used, and why it is not to be considered as a serious rival of the others we are describing.

Traction by Compressed Air.

It is impossible to better explain the position which compressed air as a motive power occupies than by quoting the report of Mr. Humblot, inspector-general of the Department of the Bridges and Roads of France. In effect, he says:

"Compressed air is not a source of power. It is in reality only a vehicle for the transmission of power in heat, which heat can retransform itself into power. In order to obtain from air an economical return, it is necessary to supply it with caloric at the moment of its utilisation by reheating, in order to compensate for the losses of every nature to which it has been subjected as a consequence of cooling after compression, in the tubes and reservoirs."

By employing compressed air in traction all the many advantages are secured which this agent has been demonstrated to possess in the mechanical applications which have heretofore been made. If there is anywhere a demand for an easily manageable motor, it is certainly for tramways. With compressed air, variations of speed are obtained with the greatest ease and without shock by the simple turning of a cock—stops are made almost instantaneously, as vehicles operated by this system naturally employ air brakes, the reliability of which is so well known.



Compressed air at high pressure is successfully employed on the Nantes tramways and upon the line from Paris to Nogent-sur-Marne. It has been recently adopted for two important lines in Paris. The Nogent compressed-air tramway carries nine reservoirs under the car. These are made of thick sheets of steel, and have a capacity of 682 gallons. The air is carried at a pressure of from 99·207lb. to 176lb. At this pressure, a total weight of from 374lb. to 660lb. of air is stored. Three of these nine reservoirs form an independent store, the high pressure of which is only used in cases where some excessive strain has to be met. The reheating of the compressed air when it leaves the reservoirs, and before it enters the motor cylinders through the pressure regulator, is effected by passing it through a receptable containing superheated water, and filled at the charging station. The amount of water carried is 44 gallons, and its temperature from 150deg. C. to 160deg. C. at starting. The weight of the Nogent car (seating 50) is 25,300lb.; including passengers, 31,900lb. Upon a single charge of air the car can run over 12 miles on an ordinary line. On the Nogent line, only 8¾ miles are made without re.

Digitized by Google

charging with air and water on account of the constant and heavy grades. The average consumption of air between Maltournee and Vincennes, where the most severe grades are encountered, is about 35lb., while upon the section from Maltournee to Ville-Evrard, where, as in ordinary railway lines, the grades do not exceed 2 per cent., the consumption of air does not exceed 24lb. per mile. When the motor-cars tow a trail-car the consumption of air increases 30 to 35 per cent. With a loaded trail-car the weight of the train is about 48,400lb.

Traction by means of reservoirs containing compressed air is, in fact, the only system which has proved itself by long practical application, and demonstrated its real economy over animal traction. Its introduction into general use has been limited by the drawbacks which we now enumerate:

1. The first of these arises from the employment of air at the high pressure of from 45 to 80 atmospheres, of which only an average of eight to ten is made use of. This occasions a useless expense in compression.

2. The second consists in the necessity of carrying upon the car numerous reservoirs, constructed of thick sheets of metal and consequently very heavy, in order to afford reservoir space for a great quantity of air at high pressure.

The latter is a serious inconvenience, for not only is a great dead-weight constantly carried at a loss, increasing uselessly the expense of traction and being superfluous for adhesion, but the great weight of the vehicle sensibly wears upon the rails and occasions rapid deterioration of the road bed. In many cases the police regulations, as in Paris, limit the weight of tramway cars. In the case of the Nogent motor—which, without passengers, weighs 25,300lb.—the nine reservoirs, having a total capacity of 682 gallons, and constructed of steel plates 0·4724in. thick, form a supplementary load of 8,800lb., which must be kept in mind when considering the cost of traction and economy of operation. In this regard, the disadvantages of the Nogent motor are quite the same as those experienced in traction by electrical accumulators, the latter suffering equally from the necessity of having to constantly carry an enormous weight which it has so far been impossible to dispense with.

3. The car used with the Nogent system is not so constructed as to allow of the use of axles independent horizontally, so that it has been found necessary to draw the axles too closely together, in order to operate over even ordinary curves. This arrangement must inevitably destroy the stability of the car, and produce a see-saw motion, which not only militates against good running, but is extremely disagreeable to passengers.

4. In this same motor-car the two reciprocating motors are placed below the level of the car body and at the sides. Their movements in the same direction being successive and alternating, there results a continual rocking motion, which is even more damaging to the rails and disagreeable to the passengers than the see-saw motion above referred to.

5. The front platform is entirely occupied by apparatus. It is consequently useless for passengers.

6. As the car can only run in one direction, turntables become a necessity. This increases first cost and maintenance, complicates operation, and wastes time.

7. It is necessary for cars of the Nogent type to take in a supply of superheated water at the same time as the reservoirs are filled with compressed air. This double operation necessitates the feeding station being placed near a boiler, which would often be impossible in a city.

8. In this system, supplies of compressed air and hot water can only be taken in at the station; this, if the trip is sufficiently long, renders the construction of one or more special stations necessary along the line. Furthermore, this supplying of the reservoirs requires considerable time, and delays the service.

Objections Nos. 1, 2, 5, 6, 7, 8 above mentioned are found as well in the electrical accumulator car.

In the new system designed by Monsieur Conti it will be found that all these objectionable features have been done away with. The motive power is furnished by compressed air at a pressure of only about 44lb. (instead of 100lb. to 175lb., as in the Nogent system), stored in reservoirs carried beneath the car. But in order to avoid giving too great a weight to the vehicle, and to correct one of the principal defects mentioned in the Nogent motors, these reservoirs are only two or three in number, and of relatively small capacity—advantages which are gained by the ability to recharge the reservoirs (without interrupting the regular service, and upon the public street) by means of automatic feeding points. These feeding points are naturally established by preference near fixed stops.

Before and after the passage of a car, a little rectangular closed cover of cast iron at the level of the roadway between the rails, is the only external sign showing the existence of the automatic feeding point. The weight of the motor-car itself when it runs over the feeding point operates a sub-surface attachment, which opens the cover and instantaneously places the subterranean conduit between the tracks in communication with the reservoir of the car requiring a reinforcement of pressure. When the car again starts its weight operates the mechanism, which cuts off communication and hermetically closes the feeding point. As a few seconds only are necessary to complete the operation of recharging, the stop will never be greater than is usual at ordinary stopping places. Under ordinary conditions the distance between feeding points will be comparatively great, or on an average every mile and a half. As it is certain that within that distance there will always be found certain points at which a car must stop to take up or set down passengers, it will be seen that recharging will have little effect upon running time. Under such circumstances a car will always be ready to do its work. It will never need (as is obligatory in systems employing superheated water, electrical accumulators, or air accumulators of the Nogent type) to run into the carshed, or to pass near a charging station, in order to stop there more or less time.

So far as renewal of motive power is concerned, everything is done not only with great rapidity, but, moreover, by the aid of sub-surface appliances. No aerial material is required. Poles, wires, anchorages, stations upon one or more points of the line to provide compressed air or superheated water, are all done away with. This system interferes in no way with co-existent services, public or private, and as a consequence encounters no difficulties in obtaining franchises from municipal authorities. Owing to the system of feeding points along the line, a single power station can supply several lines at the same time, becoming, therefore, a veritable central station for the entire network of tramways of a city.

Compared with the Nogent motor heretofore mentioned, the weight of the new car, seating 50 persons, is reduced by more than one-third, and amounts to only 15,400lb. when empty. In order to gain a still higher economy, the motor is compound and the air is reheated twice. The motor being compound (or with two cylinders), can, according to its needs at various points of the route, work with either double or single expansion. By means of a special regulating apparatus, the several combinations by which the compressed air is admitted into the motor cylinders—for starting, regulation of power and speed, stopping, and brakes—operate in a cycle perfectly established and controlled. The various parts of the regulating apparatus are operated by a single handle, and only require in consequence a single movement.

The car body is mounted upon two independent frames, each one carrying an axle driven centrally by one of the two compound compressed-air motors, and having, moreover, freedom of motion around a vertical axis passing through its centre. Thus the two axles, each driven by a compound motor, are independent horizontally, which permits the operation of sharp curves. Moreover, as each motor drives upon the centre of its axle, all rocking motion is avoided completely. Furthermore, in order to avoid dead centres, and to share the work equally between the two axles, these are bound together by a special mechanical arrangement which keeps the angle of the cranks constant, the axles remaining always independent of each other horizontally.

The entire mechanism is hidden beneath the car body. The body itself remains completely independent of the frame upon which it rests. The platforms are entirely free. The driver on the front platform has nothing whatever to do but to operate two controlling handles. The car runs equally well in either direction. At a terminus the driver moves to the other platform carrying with him the two handles. The expense and inconvenience of turntables is thus avoided.

Cost of Production of Compressed Air and its Utilisation as a Motive Power for Tramways.

The cost per horse-power hour in compressed air reduced to atmospheric pressure, and utilised by motors of from 15 to 20 effective horse-power, has been established by numerous trials in Paris. Motors of the above power are principally employed in mechanical traction for tramways. The consumption of compressed air in a compound motor, such as is employed in the "Conti" system, the air being reheated before its admission to the cylinders to a temperature of 160deg. C., is 11·300 litres (9 944 gallons) per horse-power hour developed at the axle of the vehicle. To this cost it is necessary to add the losses in the distributing pipes, small escapes which may happen in the mechanism, and also the cost of operating the wheel brakes. We can assume a maximum loss of 10 per cent., which would put the actual consumption of air per horse-power hour at 12·430 litres, or 16·278 cubic yards.

Summary.

1. Steam horse-power hour at the station where the air is compressed, drawn in and compressed at a pressure of 20 kilos, or 44·091b. = 5·273 litres, or 6·897 cubic yards.

2 Amount of fuel at the station per horse-power hour including heating, pumps, accessories, etc., 1 kilo, 200 grammes, or 2·62lb.

3. One compressed air horse-power hour at the axle of the vehicle cost in atmospheric air 12·430 litres, or 16·278 cubic yards.

4. For reheating the air per horse-power hour 0·200 gramme, or 0·42lb.

5. The result of operating the Nogent lines of tramways by compressed air establishes the fact that a car loaded with 52 persons, upon a line 13 kilometres, or 14,207 yards, with maximum grade of 52 millimetres per metre, requires 8·800 litres, or 11·510 cubic yards of compressed air per car kilometre. (A kilometre equals 1,094 yards.)

Conclusions.

It is clear that a new system of mechanical traction for tramways will have chances of adoption proportionate to its gain in economy of operation: reduction in expenses being desirable at once in cost of production at the station, in the motor, and in the consumption by the motor of power. But it is also necessary that the system be easy to work and direct, and, moreover, absolutely beyond the possibility of sudden interruption from accident. It is also necessary that the system proposed should be easily understood by any tramway operator, and that it should not be necessary to preface its consideration by long special technical study.

In the present state of the art of mechanical traction as applied to tramways, it is evident that if economical operation be desired, the supply of power from a central station is indispensable. Operation by electric conductors carries with it many difficulties for the operator, largely arising from the inevitable complications

Digitized by Google

of a service requiring such special knowledge as to make an expert technical staff in constant surveillance a necessity. With compressed air the method of operation is so simple that there is no necessity for long study of an expert nature before undertaking the handling of that system, while it is at the same time so regular and sure that one is not kept constantly on the alert, as is the case with the electric line. It follows that the manager of a compressed-air tramway can really direct its operation without being always at the discretion of an engineering staff, since he is free from apprehension of any serious trouble in his service. To handle an air-compressor is as simple as a pump. Any ordinary mechanic can undertake its management. The air being stored in advance in great quantities at a time in the reservoirs of the central station, in the distributing pipes, and in the tanks of the motor, interruption of service is practically impossible.

One of the most important advantages of compressed air is that it lends itself so well, incomparably better than any other system, to direct storage, which quality admits of holding in reserve great accumulations of energy with so much ease and economy. So far as accumulation of reserve power is concerned, electricity has incontestably shown itself greatly inferior to compressed air. Moreover, with compressed air, one has not to dread the deterioration of generating apparatus at the station on account of the sudden strains to which it is subjected by the interruption of current at the moment of stopping the motor, as is the case with an electric system. The reactions which so often have such disastrous effects upon generating dynamos are completely absent from compressed air generating apparatus. The latter being thus free from one of the most serious causes of deterioration, can, in contrast with electric installations, be operated for long periods without repairs. It should be also borne in mind that where the elevated electric conductor is employed, the operation of the line is always exposed to serious interruption. It is always possible for an evil-disposed person to throw the whole line out of service. It is unnecessary to rehearse here the many other objections to the use of the aerial wire.

As we have already stated, the result of the numerous comparative trials demonstrates that the cost of traction by compressed air is not higher than with the trolley-wire system. It would seem undeniable that, at the same cost, the compressed air system possesses undoubted advantages over the electric in all that regards the convenience, the comfort, and the security of the public.

THE ROYAL COMMISSION ON ELECTRICAL COMMUNICATION WITH LIGHTHOUSES AND LIGHT-VESSELS.

THE SECOND REPORT OF THE COMMISSION.

In our last issue reference was made to the fact that the Royal Commission appointed to enquire what lighthouses and light-vessels it is desirable to connect with the telegraphic system of the United Kingdom by electrical communication, had issued the second report. The members of the Commission are as follows: the Earl of Mount-Edgcumbe (chairman), Mr. Henry Lyle Mulholland, Sir Edward Birkbeck, Bart., Sir F. L. McClintock, Sir G. S. Nares, Mr. W. H. Preece, Mr. J. C. Lamb, Mr. John A. Kempe, and Mr. R. Munro-Ferguson. The following is the second report:

Since the issue of our first report, we have made a further tour of inspection of lighthouses and light-vessels. On July 10, 1893, we assembled at Glengariff, Bantry Bay. On the following morning we embarked on board the steamer "Moya," which was placed at our disposal by the Commissioners of Irish Lights, and inspected the Bull Rock and the Fastnet. Leaving the "Moya" at Baltimore we proceeded to Cork, and thence to Kingstown, where we embarked on board H.M.S. "Enchantress." On the morning of July 13 we proceeded to the Isle of Man, landed at the Chicken Rock Lighthouse, and, passing Langness Lighthouse and the Bahama Bank light-vessel, anchored in Ramsey Bay. On the following day we crossed from the Isle of Man to Bangor, county Down, passing the South Rock and Skulmartin Rock light-vessels and Mew Island Lighthouse. On July 15 we proceeded to Lamlash, landing on the way at the Maidens and Ailsa Craig Lighthouses. After having visited Pladda Island Lighthouse, we landed on July 17 on Sanda Island and Rathlin Island, inspecting the lighthouses on those two islands, and anchored for the night in Lough Foyle. From Lough Foyle we proceed to Oban, after having inspected the lighthouse on Inishtrahull Island, and from Oban we steamed through the Sound of Sleat to Stornoway. Returning to the mainland, we anchored at Loch Inver, and visited the Ru Stoer Lighthouse, and on July 24 we left Loch Inver for Longhope in the Orkney Islands, whence we paid a visit to the Cantick Lighthouse and to the look-out station of the Commissioners of Northern Lighthouses on Brough Ness, opposite to the Pentland Skerries Lighthouses. On July 26 we inspected Stroma and disembarked at Scrabster. Then proceeding south by train to Seahouses, we embarked on board the Trinity House steamer "Argus," which conveyed us round the Farn Islands. The tour of inspection ended with the visit to the lighthouses on those islands. We reassembled in London in September, and have since held several meetings.

Although the general question of signalling had not been directly referred to us, it appeared to be so intimately connected with the subject of electrical communication that we felt ourselves justified in considering it, and in our first report we stated that in cases "where the distance from the shore is not great, an improved system of distress signals (distinct from the usual fog signals) might, both at rock stations and on light-vessels, prove an effective temporary substitute for the more costly expedient of electrical communication." This view has been confirmed by the experience which we gained during our last tour of inspection, and we are now prepared to go further and recommend that the general lighthouse authorities should be invited to consider the subject with the view of instituting a universal system of visual and sound signals at all the various light stations on the coasts of Great Britain and Ireland. A member of the Commission, Sir Edward Birkbeck, having occasion last spring to visit the United States of America, we requested him to take the opportunity of enquiring into the systems of coast communication in force in Canada and the United States. On his return to this country, Sir Edward Birkbeck submitted to us a report, a copy of which will be found in the appendix. From that report it will be seen that, while both Canada and the United States possess an efficient system of electrical communication round their coasts, none of the light-vessels belonging to those countries had been electrically connected with the mainland.

We have received and considered particulars of a number of inventions for effecting electrical communication between light-vessels and the shore, but none of these are, in our opinion, preferable to the "Sunk" system, which is now being applied to the Goodwin (north sand head) and Kentish Knock light-vessels. We have again to express our obligation to the Admiralty for the loan of H.M.S. "Enchantress," and to the Trinity House, the Commissioners of Irish Lights, and the Commissioners of Northern Lighthouses for the assistance which they have rendered to us.

Recommendations.—We recommend that electrical communication by aerial wires be established without delay between the telegraphic system of the country and the following shore lighthouses and lighthouse stations:

Name of lighthouse.	To be connected by telephone with	Estimated cost (approximate).
Falmouth Harbour	Portscatho C.G.S.	£160
Souter Point	Whitburn C.G.S.	100
Montrose (Scurdy Ness)	Usan C.G.S.	85
Covesea Skerries	Lossiemouth P.O.	83
Tarbet Ness	Portmahomack P.O.	55*
Look-out station at Brough Ness for Pentland Skerries Lighthouses	St. Margaret's Hope P.O.	233
Fair Isle (north end)	Fair Isle P.O.	128
Sumburgh Head (Shetland Islands)	Sumburgh P.O.	65
Cape Wrath	Durness P.O.	20*
Ru Stoer	Stoer P.O.	20*
Rhynns of Islay (Oversay Island)	Bruichladdich P.O.	330
Turnberry	Maidens P.O.	48
St. Bees	St. Bees P.O.	76*
Langness	Castletown P.O.	103
Menai	Beaumaris P.O., and lifeboat coxswain's house at Penmon.	72
South Stack	Holyhead C.G.S.	15
Galley Head	Dunny Cove C.G.S.	150
Loop Head Kilcradan Point	Carrigaholt P.O.	61*
Total		£1,804

* If Admiralty wire is used.

It is with regret that we have decided to confine our recommendations in this report to shore lighthouses, but until more has been done towards effecting the connection of those light-vessels and lighthouses which were selected in our first report as having the strongest claims to immediate attention, we hesitate to add to the list of light-vessels and island and rock lighthouses with which we consider that electrical communication should be established.

THE PACIFIC CABLE SCHEME.

In view of the Colonial Conference to be held in June at Ottawa (says the *Times*) at which the scheme for a cable between Australia and Canada is to be considered, representations have been lately made to the Colonial Office. The advocates of the undertaking urge that the British Government should unite with the Governments of Australasia and Canada in guaranteeing the interest upon the capital required for a single line of cable. The Intercolonial Conference at Wellington considered that a guarantee of 4 per cent. upon a capital not exceeding £1,800,000 for 14 years would be sufficient to induce a company to undertake the construction of the line. But Mr. Sandford Fleming, the chief Canadian promoter of the scheme, thought that a joint guarantee of 3 per cent., representing a total charge of £52,350, would be sufficient, while the Colonial Conference thought £72,000 would be needed. Mr. Sandford Fleming suggests five routes, his object being to touch only at places where British influence is supreme. But the Wellington Conference proposed

Digitized by Google

that the cable should touch at both the Sandwich Islands and Samoa.

In opposition to the scheme important representations have been submitted to the Marquis of Ripon on behalf of the cable companies which control the existing lines between the United Kingdom and Australasia. They urge that the existing service was established solely by private enterprise, no Government subsidy, guarantee, or exclusive landing rights having been granted to the company. A cheap tariff was tried in 1891-92 and resulted in a loss of £55,000, borne equally by the guaranteeing Australian Governments and the company. For the second year the loss amounted to £43,500, when the Governments concerned were instrumental in raising the tariff from 4s. to 4s. 9d. on January 1, 1893. The loss for the current year is estimated at £12,000. It is urged that as the present cable is duplicated throughout, and capable of carrying a far greater traffic than at present, an additional service is not wanted, and that the cost of £2,000,000, or £4,000,000 if duplicated, would end in ruinous competition. Moreover, if the Imperial Government joined in the proposed guarantee it could not in equity refuse to assist the existing service to the same extent. Any diversion of route would also inflict a heavy loss on the Indian Exchequer. The present traffic between Europe and Australasia consists, roughly, of 1,300,000 words per annum, and is worth about £209,000 a year. If the tariff was reduced to 3s., this amount would be reduced to £119,000, leaving a loss of £90,000. If half the traffic was diverted *vid* the Pacific, this loss would be increased to £150,000. On the other hand, a Pacific cable carrying half the existing traffic would, it is urged, only earn at a 3s. tariff about £45,000, after deducting out-payments. On the other hand, in order to meet its liabilities, it would have to earn £237,000, as shown in the following table :

Capital		£1,800,000
Working expenses	£25,000	
Maintenance	35,000	
		£60,000
Amortisation to replace cable at end of 14 years' guarantee		105,000
Four per cent. interest on capital		72,000
		£237,000
Leaving—after deducting estimated earnings as above	£45,000	
And the proposed 4 per cent. guarantee	72,000	
		117,000
A deficit of		£120,000

RESULTS OF EXPERIMENTS WITH THE HERMITE SYSTEM AT BREST.

We have received a copy of a report translated from the French and relating to experiments made at Brest with electrolysed sea-water prepared according to the Hermite system. The report, which has been presented to the Municipal Council of Brest, has been drawn up by Dr. Piton. After detailing the experiments, Dr. Piton says :

Summary.

From all these experiments that I have made it follows :

1. That electrolysed sea-water is relatively stable, and the higher the strength the greater the stability.

At 1 gramme per 1,000 it loses $\frac{1}{10000}$ per day.
At 0·75 " " $\frac{2}{1000}$ "
At 0·50 " " $\frac{3}{1000}$ "
At 0·25 " very unstable.

At the end of 24 hours' solution at 0·25 gramme contains an exceedingly feeble quantity of chlorine.

2. That the mixture of electrolysed sea-water with sea-water is very unstable.

3. That the mixture of electrolysed sea-water with fresh water is as stable as if two electrolysed solutions were mixed together, showing the possibility of transporting a concentrated solution to a distance, and reducing the strength with fresh water at the point required for use.

4. As a deodoriser the electrolysed sea-water is perfect.

5. That electrolysed sea-water does not dissolve fæcal matter, or paper, appreciably.

6. That it requires : (*a*) six litres of electrolysed sea-water at one gramme to sterilise one stool of 150 grammes ; (*b*) seven litres at 0·75 ; (*c*) nine litres at 0 50 ; (*d*) 10 litres at 0·36 ; (*e*) 12 to 15 litres at 0·25.

7. That electrolysed sea-water at one gramme, given equal volumes, is sufficient to sterilise a liquid stool in five minutes.

8. That it only take five minutes with solution from 1 to 0·75 to sterilise, in equal volumes, a culture of pure cholera or typhoid bacillus.

9. That it takes 10 minutes, with an equal volume of solution at 0·5 gramme and cholera bacillus, to sterilise the latter.

10. That it requires 15 minutes with solution of one gramme, and with equal volumes, to sterilise the "bacillus subtilis."

11. That an intimate contact is absolutely necessary—showing the necessity of retaining the materials in a cesspool or syphon before allowing it to run into the drain.

Conclusion.

The experiments that I have made lead me to the conclusion that electrolysed sea-water is a perfect deodorant and an excellent antiseptic, which rapidly destroys the most hardy micro-organism, always assuming a good contact between the micro-organism and the electrolysed solution.

In closing this report, I must request Dr. Vergos, doctor of the first class in the navy ; Dr. Parin, doctor to the colonies ; and Drs. Taburet and Ruelle (doctors of the navy), to accept my best thanks for their kind assistance in enabling me to finish these experiments rapidly upon the effect of the electrolysed sea-water upon the bacteria.

VESTRY OF ST. PANCRAS.

The following is an abstract of the published statement of accounts at December 31, 1893, under the St. Pancras Electric Lighting Order, 1893 :

Capital Account at Dec. 31, 1893.

Dr.	Expenditure to Dec. 31, 1892. £ s. d.	Expended during the year. £ s. d.	Total expenditure to Dec. 31, 1893. £ s. d.

LEGAL INTELLIGENCE.

EBBSMITH v. DAWSON AND OTHERS.

The action brought by Ebbsmith *v.* Dawson and others came before Lord Justice Coleridge and a jury on Wednesday. The case arose out of certain matters in connection with the South Staffordshire Tramways Company and the Electric Construction Company.

Sir Edward Clarke, Q.C., and Mr. G. Spencer Bower were for the plaintiff; and Mr. Murphy, Q.C., Mr. Blake Odgers, Q.C., and Mr. Hugh Fraser for the defendants.

Sir Edward Clarke, in opening the case, produced the circular containing the alleged libel, which in February, 1893, was issued by the defendants, who constituted the shareholders' committee of the tramways company, to their shareholders. This stated that whilst the shareholders in the South Staffordshire Tramways Company were being gradually educated to the idea of electric propulsion, and their authority obtained for the introduction of the necessary parliamentary measures, arrangements were being made in another quarter, apparently with the object of turning the profit to a good account, as on May 29, 1889, a company was registered in London under the title of the Electric Construction Company, in which Mr. Joseph Smith (now Ebbsmith), the present plaintiff, appeared as managing director, with a holding of £4,260, as against £200 in the tramways company, and that his former partner, Mr. George Roseurs, was the registered owner of £20,000, as against two shares held in the South Staffordshire Tramways Company, and the chairman of the latter company, Mr. Carruthers Wain, was holder of £3,000, as against £500 in the electric company. The circular further stated: "We find that Mr. Joseph Smith occupied the position of managing director until 1892, from the commencement of which his name ceased to be put forward in reports of the corporation, and it is curious to observe that Mr. Jabez Spencer Balfour and Mr. Henry Granville Wright, of Liberator notoriety, disappeared from the directorate at the time, and, for some reason or other, Mr. Smith changed his name at the end of 1892 by adding the prefix 'Ebb' to it; so that he is no longer Smith, but Ebbsmith." Sir Edward went on to say that the only conclusion which anybody could come to on reading the paragraph was that Mr. Smith, in using his earlier name as managing director of the Electric Construction Company, did so for the purpose of making money out of the South Staffordshire Company, and his interest in the Electric Company being so large, and his interest in the other so very small, he had made an arrangement for the benefit of the Electric Company. There was thus not the slightest foundation for the suggestions which had been made.

Mr. Ebbsmith was called, and corroborated counsel, stating that he changed his name at the request of his maternal grandmother, who was named Ebb.

The case was adjourned.

COMPANIES' MEETINGS.

EASTERN EXTENSION TELEGRAPH COMPANY, LIMITED.

The forty-first ordinary general meeting of the Eastern Extension, Australasia, and China Telegraph Company was held on Wednesday at Winchester House, Old Broad-street, Sir John Pender, M.P., in the chair.

The **Chairman**, in moving the adoption of the report and statement of accounts, reviewed at length the position and the prospects of the Company. The reduction in the expenses was partly due to the lower outlay in cable repairs, and partly to the increased revenue resulting from the raising of the Australian tariff, which was done at the request of the colonies, from 4s. to 4s. 9d. per word, and to the exceptionally heavy Australian traffic transmitted during the financial crisis last summer in connection with the numerous bank failures and reconstruction schemes. But for this there would have been a considerable falling off in revenue. The agitation for a Pacific cable between Canada and Australasia had greatly increased of late, but he did not think it would result in anything, as the line was too costly, and was not in reality required. The Governments interested had been advised by a conference held at Wellington to offer a guarantee for 14 years of 4 per cent. on a capital of £1,800,000, on condition that the tariffs were reduced to 3s. per word for ordinary telegrams, 2s. per word for Government telegrams, and 1s. 6d. per word for Press messages, but the cost of a duplicate line on that route would be £4,000,000,

Digitized by Google

and was an unnecessary waste of money. But if such a line were subsidised, as their line was established by private enterprise, her Majesty's Government could not in equity grant pecuniary aid to such an undertaking without subsidising or guaranteeing their cables to the same extent. If, however, such a line was wanted for strategic purposes, it would be cheaper for the Governments concerned to arrange with them to do the work.

The **Marquis of Tweeddale** seconded the motion, which was passed.

COMPANIES' REPORTS.

METROPOLITAN ELECTRIC SUPPLY COMPANY, LIMITED.

Report of directors to be presented to the shareholders at the seventh ordinary general meeting to be held at Winchester House, Old Broad-street, E.C , on Monday, April 23, at 12 o'clock noon.

The directors submit a statement of the Company's accounts for the year ending December 31, 1893, prepared in the form prescribed by the Board of Trade, under the provisions of the Electric Lighting Acts of 1882 and 1888. The capital expenditure, which at the end of 1892 amounted to £550,859. 16s. 11d., now shows a total of £585,932. 8s. 9d., being an increase during the year of £35,072. 11s 10d , principally owing to the continually growing extension of the Company's mains, to the cost of transformers and meters, and to providing connections to the premises of new consumers. The expenditure on buildings and machinery includes further payments on account of the Paddington plant, the sinking and fitting of a well for the more economical supply of water to the Sardinia-street station, and to works found necessary in connection with the foundations of the machinery at Manchester-square station. The gross revenue for the year amounted to £69,195. 4s. 4d., against £54,571. 19s. in 1892, being an increase of £14,623. 5s. 4d. as compared with the actual increase of £13,851. 19s. in 1892. A larger increase was fully expected, but the exceptional brightness and absence of fogs during the winter months had a serious effect in diminishing the demand for light In proof of this, it may be mentioned that while the revenue during each of the first three quarters of the year showed an increase of nearly 50 per cent over the corresponding periods in 1892, the increase for the last quarter was only 8 per cent., although there was no falling off in the growth of the lamp connection. The balance to the credit of the revenue account, before providing for depreciation, is £22,913. 15s. 2d. The directors have set aside £7,000 as an addition to the depreciation fund, carrying to the credit of the net revenue account the sum of £15,913. 15s. 2d., which, with the balance brought forward from the last account, and other receipts, make a total of £18,512. 16s. 4d. After deducting bank charges and debenture interest, there remains a balance of £14,548. 19s. 4d., of which the directors, in pursuance of the policy commenced last year, have appropriated a further sum of £1,000 in reduction of the preliminary expenses account, which is now diminished to £3,052. 10s. 4d. The directors recommend that a dividend of 5s. per share on the ordinary share capital be now paid, which will absorb a sum of £12,475, and leave a balance of £1,073. 19s. 4d. to be carried forward to the next account. The number of 8-c.p. lamps supplied by the Company increased during the year 1893 from 124,000 to 166,000. The present number of lamps connected is 175,000, and further applications continue to be received in satisfactory numbers. A report from the Company's chief engineer is appended, showing that the satisfactory condition of the stations, machinery, and plant has been maintained. The directors have to record, with the deepest regret, the death of two of their valued colleagues, Sir James Anderson and Sir George Elliot, both of whom had been members of the Board from the commencement of the Company. It is not proposed at present to fill the vacancies thus caused. In accordance with the articles of association, the following directors—viz., Admiral of the Fleet Lord John Hay, G.C.B., Joseph Charles Parkinson, Esq., and John Denison Pender, Esq.—retire from the Board, and, being eligible, offer themselves for re-election. The auditors, Messrs. Deloitte, Dever, Griffiths, and Co., also retire, and offer themselves for re-election.

Report of Chief Engineer.—I have pleasure in certifying that the Company's stations, machinery, and plant are being maintained in a satisfactory condition, and have worked without interruption up to the present date.

FRANK BAILEY, Chief Engineer.

BUSINESS NOTES.

Western and Brazilian Telegraph Company.—The receipts for the past week were £2,603.

Hobart Electric Tramway Company.—For the month of March the earnings were £1,416.

Liverpool Overhead Railway.—The traffic receipts of this railway for the week ending 15th inst. amounted to £655.

Renfrew.—A large dredger launched by Messrs. Simons for the Russian Government is lighted throughout by electricity.

Sale of Plant.—Particulars of second-hand electric lighting plant for sale will be found in our advertisement columns.

West India and Panama Telegraph Company.—The receipts for the two weeks ended April 15 were £315 less than for the corresponding period of 1893.

Tenders for Exminster.—As will be seen by our advertisement columns, the Committee of Visitors of the Devon County Asylum desire samples of materials for wiring the asylum.

Southport.—No less than 1,400 yards of low-tension mains have been laid in the streets out of a total of 5,295 yards. The delivery of the high-tension mains was expected yesterday.

Tenders for St. Pancras.—It will be seen from our advertisement columns, that the St. Pancras Vestry invite tenders for the buildings to contain electrical plant at King's-road.

Fleetwood.—At a meeting last week of the Improvement Commissioners the clerk (Mr. J. Tidsley) said that complete specifications for the construction of the buildings had reached him.

Lancaster.—A circular has been issued by the Corporation informing intending customers for electric current that it was intended to commence a continuous supply on Tuesday last.

Eastern Telegraph Company.—The Company announce the payment by warrants on May 1 of interest for the half-year ending April 30 on their 4 per cent. mortage debenture stock.

Wakefield.—At a meeting of the Town Council, in reply to a question as to when the town would have the electric light, the Mayor explained that the provisional order had not yet been obtained.

Bedford.—Mr. Medhurst, the engineer, has been requested by the Town Council to draw up plans and estimates, with a view to tenders being invited for the erection of the central station and the supply of the plant.

Sale of Current.—The current sold by the St. James's and Pall Mall Electric Light Company, Limited, for the quarter ended March 25, amounted to £10,375, as against £10,119 in the corresponding period of 1893.

Islington.—At a meeting of the Islington Vestry last week the Clerk reported in regard to the electric lighting station site in Holloway-road that the mortgage for £9,000 with the London County Council was completed.

Southend Lighting.—An agreement with the gas company for public lighting has been sealed upon the town clerk's advice that it would in no way interfere with the lighting of the borough with electricity should such a decision be arrived at.

Tenders for Brighton.—As stated in our last issue, the Town Council invite tenders for the supply and erection of Willans engines, continuous-current dynamos, pipe work, spare armatures, etc. Tenders are to be sent in by the 30th inst.

Buxton.—At the last meeting of the Local Board there was a long discussion on the question of the town being lighted by electricity. The Chairman said nothing definite had been done so far. It was agreed to have a special meeting *re* the electric light.

Dover.—The surveyor has submitted to the Town Council the drawing he had received from the electric light company of the lamp columns, and it has been approved. The columns are of similar design to the large lamps on the sea-front, only that they are 21ft. in height.

A Wharf Crane Required.—As mentioned last week, tenders are required for a travelling jib landing crane, and also for a dynamo and lighting installation. Applications are to be sent to Messrs. C. H. Glover and Co., Hatcham Sawmills, Ormside-street, Old Kent-road, S.E.

Award.—Mr. H. Tompkins, in connection with the exhibition of blacksmiths' work held last week at the Ironmongers' Hall, Fenchurch-street, E.C., was awarded a prize for a handsome electrolier. Several electrical fittings in hammered iron were lent by a member of the Blacksmiths' Company.

Morecambe.—Complaints have been made to the Morecambe Local Board of alleged "stinks" from the electric light company's works, said to be due to the discharge into the air of the superfluous water gas. The medical officer has been instructed to report on the matter.

Bengal.—It appears that the agreement among the Bengal jute manufacturers is to run the mills only five days per week for three months from April 2. The owners of the Hastings mill have declined to join the movement at all, and the mill is being fitted up with the electric light for night work.

Ashton.—The Market, Lighting, and Cemetery Committee of the Town Council are of opinion that the question of electric lighting ought to be now considered, and they have requested the chairman of the General Purposes Committee to convene a meeting of the said committee to consider the matter.

City and South London Railway.—The receipts of the Company for the week ended April 15 were £840, against £861 for

Digitized by Google

the same period last year, or a decrease of £21. The total receipts for the first half-year of 1894 show an increase of £9 compared with those for the corresponding period of 1893.

St. Pancras.—The tender of Messrs. Easton, Anderson, and Goolden for the supply of boilers for the King's-road electricity station, at £2,837. 6s. 2d., has been accepted. The tender of Messrs. Doulton and Co. for supplying the electricity station with a water-softening apparatus for £198, has also been accepted.

Edinburgh.—The following are the contractors for the supply of cables in connection with the Edinburgh Corporation's electric light station: unarmoured cable, Henley's Telegraph Works Company, Limited; arc lighting cable, Indiarubber and Telegraph Works, Company, Silvertown; armoured cable, Messrs. Siemens Bros.

Yarmouth.—A special sub-committee of the Town Council has been appointed to consider the present lighting of St. Andrew's Ward, and to report as to whether any improvement could be obtained in the quality and cost of the gas supplied to this ward. The Electric Lighting Committee have also been invited to make a report.

Chadburn and Son, Limited.—This Company has been registered with a capital of £30,000 in £1 shares, to enter into an agreement with William Chadburn, and to acquire and carry on the business of a patentee and manufacturer of ships' telegraphs, optician, and nautical instrument maker, now carried on by him at Liverpool.

Coventry.—At a meeting of the City Council a letter was read from the Electric and General Contract Corporation, Limited, asking the Corporation to delay taking any steps in the matter of the tramways for one month pending negotiations for the equipment of the line. It was ordered that the matter stand over for one month.

New Company—The business of Mr. John T. Bolding, trading at Grosvenor Works, Davies-street, London, W., as brassfounder and manufacturer under the title of John Bolding and Sons, has been converted into a private limited company. No shares will be offered to the public, all the shares being held by Mr. Bolding and the employés.

Clerkenwell.—The County of London and Brush Provincial Electric Lighting Company, Limited, are about to commence work in Clerkenwell. The Vestry has received a letter from the company to this effect, and also that the whole of the 19,900 shares of £10 each offered for subscription by the company have been allotted.

Windsor.—At a meeting last week of the Urban Sanitary Authority, Alderman Hollis said he was sorry to see no report from the Electric Light Committee appointed some time since. It was time something was done. The Deputy Town Clerk said communications had been made of the nature of which it would not be wise to make public.

Notting Hill.—The Notting Hill Electric Lighting Company have applied to the Kensington Vestry for permission to lay mains in a road which was not in the area specified by their provisional order, and the Vestry have informed the company that they would be prepared to consider any proposal that the company might make for dealing with a larger area.

Phosphor Bronze Company.—The twentieth annual general meeting was held on the 30th ult., Mr. Henry Seebohm in the chair. The directors' report and accounts were adopted. Mr. C. E. Taunton handed in his resignation as a director. Mr. Bernard Gibson was re-elected, and Messrs Francis W. C. Cuming and Richard E. M. Lagerwall were appointed directors, the last named to be a managing director.

Cockermouth.—The minutes of the Gas Committee presented at a meeting of the Urban Sanitary Authority last week, contained a recommendation that a new purifier, etc., be erected. Mr. Jefferson thought the expenditure of £1,000 on extensions of the gasworks in a place like Cockermouth was money thrown away. He asked how much the electric light would cost. The Chairman said the Board had been strongly advised not to go in for the electric light.

Electric Lighting at Richmond.—We learn that almost the whole of the best work in Richmond has been carried out by Mr. C. A. Hemingway, and among the many installations which he has up to the present completed may be mentioned the Greyhound Hotel, the Castle Buffet, Marshgate House (for Alderman Robinson), 5, Hill-street (for Wm. Burrell, Esq.), and about 15 business establishments. Mr. Hemingway has a large amount of work now in hand, and has already found it necessary to extend his premises.

Steam-Turbine for Electric Lighting.—A trial has been made at Messrs. Mavor and Coulson's electric works in Glasgow of the first of Laval's steam-turbine introduced in Scotland. The rate of speed is said to be the highest that a spindle has ever been run in machinery, and the steam acts upon the turbine by impact exactly as water does. The machine is largely used in Sweden for industrial purposes, but in this case it has been specially constructed for the electric light. Lord Kelvin has examined the turbine at work.

Tenders for Southampton.—The Southampton Harbour Board invite tenders for work comprised in the electric lighting of the Town Quay, Southampton. Plans may be seen and specifications and forms of tender obtained at the offices of the engineer, Mr. J. G. W. Aldridge, A.M.I.C.E., 9, Victoria-street, London, S.W., and 23, High-street, Southampton, upon payment of £2. 2s. (to be returned on receipt of a bona fide tender). Tenders to be delivered to Mr. A. H. Skelton, clerk, at the offices of the Board, Town Quay, Southampton, by May 8.

Edinburgh.—As we have already mentioned, an extension of the public lighting is being agitated for in Edinburgh. On Tuesday at a meeting of the Town Council, a letter was read from Mr. Robert A. Douglas, with a statement in favour of including George-street, St. Andrew-square, Charlotte-square, and the streets leading into these thoroughfares from Princes-street, in the electric lighting scheme. A deputation was heard on the subject. The deputation were informed by the Lord Provost that the matter would receive the attention of the Electric Lighting Committee.

Stafford.—At a meeting of the Town Council, the Electric Light Committee recommended the following tenders for acceptance: for the electric works—engines, Messrs. Robey, £2,288; boilers, Messrs. Hicks, Hargreaves, and Co., Bolton; dynamos, the Electric Construction Company, Wolverhampton, £1,151; buildings, Mr. J. Lovatt, Wolverhampton, £3,030; ironworks and roofs, Messrs. Rubery and Co., Darlaston, £197. The report was adopted, but owing to some misunderstanding about the tender of Messrs. Robey for the engines, this part was referred back to the committee.

New Installations in Manchester.—Messrs. Baxendale and Co., of Miller-street, Manchester, inform us that they have secured the following contracts: arc and incandescent lighting at Messrs. Hepworth's shops, Market-street, Manchester; incandescent lighting at Mr. Hedley, hairdresser, Fountain-street, Manchester; additional lighting at Messrs. Scarfpin and Co., Oldham-street, Manchester; incandescent lighting at Messrs. Hall and Co., Oldham; telephonic communication with fire station at Chorley Workhouse, Chorley; and telephonic installation at Messrs. Booth and Co., Hall-street, Manchester.

Dublin.—The Corporation on Monday adopted the report of the Electric Lighting Committee, submitting a statement of the income and expenditure from January 1 to December 31, 1893, inclusive. Mr. Robinson, in moving the adoption of the report, said he thought they had reason to congratulate themselves on a very satisfactory state of affairs. If they were a private company the city accountant told them that they would be able to pay a dividend of 4½ per cent., which was very satisfactory for a new undertaking. He hoped in a few years to make substantial profits; and he might say that, comparing matters with English municipalities, they were able with a small capital to supply the same quantity of electricity. With an extension of the plant they hoped to make their working more profitable still.

Bristol—The Electrical Committee of the Town Council have determined upon purchasing a small engine and dynamo, at a cost of £613, for the purpose of supplying the small amount of current demanded in the daytime. With this new machinery it is expected that a saving of about £400 per annum will be effected. A letter was read from Mr. Arthur W. Ranken resigning his appointment of chief assistant engineer. The committee accepted the resignation, and decided to promote Mr. E. H. B. Tyler (third assistant engineer) to the vacant appointment. The committee considered applications for the vacancy caused by Mr. Tyler's promotion, and appointed Mr. G. Gilbert Bell, of Lincoln, at weekly wages of £2. On a proposal to light St. Mary Redcliffe Church by electricity, the engineer was instructed to make enquiries as to the probability of the light being adopted by tradesmen and others of the neighbourhood in order that the scheme might be successful financially, and also to make enquiries and ascertain the financial prospect of extensions to Redland, Clifton, North-street, and Stoke's-croft.

Restaurant Lighting at Edinburgh.—An electric light installation has been carried out in the Grand Restaurant, Edinburgh, by Mr. Matthew Buchan, of the Waverley Electric Works, Portobello. On the occasion of the starting of the installation, Messrs. Daish and Co., the proprietors, entertained a large number of friends to dinner. Being the first restaurant in Edinburgh to be lighted by electricity, considerable interest was taken in the event. The chairman, Mr. H. G. Younger, was presented with a "Waverley" electric watch nightlight—a bedroom appliance, by which a person may, by touching a button, be able to perceive the time without difficulty. The motor is a gas-engine of the Otto type, and capable of developing 8½ b.h.p. From one of the flywheels a flexible link leather belt is used to drive the dynamo, which is of the compound-wound self-regulating type, as manufactured by the Electric Construction Company. It is designed to give a current of 50 amperes at 100 volts pressure when running at a speed of 1,150 revolutions, and is capable of lighting about 85 16 c p. incandescent lamps or their equivalent.

Fareham.—At a meeting of the Local Board last week, the following letter was read by the clerk from the secretary to the Fareham Electric Light Company, Limited: "At the annual general meeting of the shareholders of this company, held on Wednesday, March 21st ult., a resolution was passed authorising the directors to offer their business to the town of Fareham. I am, therefore, instructed to offer the business of the Fareham Electric Light Company, with all buildings, plant, machinery, mains, meters, and all other electrical and mechanical apparatus appertaining thereto, together with their provisional order, which secures to the company the sole and exclusive right to vend electricity within the Fareham Urban Sanitary Authority for a term of 42 years, as from the year 1892. The company are prepared to sell, and hereby offer to sell the aforesaid business, either at the cost price of the same as standing in the books of the company, or by valuation in the usual way, as your Board may consider advisable." The Chairman remarked that he was in rather an anomalous position, being the chairman of the electric lighting

Digitized by Google

company. They would, however, remember that some years ago the gas company made a similar offer, and it was considered at a public meeting of the ratepayers. He thought they would have to take a similar course now. Mr. Sandy said it was clear that the Board could not determine the question. Mr. Abraham and other members agreed with Mr. Sandy, and it was resolved that a public meeting should be called on the 26th inst.

Taunton.—A report has been presented by a committee on the electric light to the Town Council, and has been adopted. The new engine and alternator are now being used at the works for the light loads. This will decrease the cost of working. The Government inspector has ordered that the belts and wheels at the works shall be fenced. Tenders have therefore been obtained for doing the work, and the committee have accepted that of Messrs. Allen and Son for the sum of £39. 7s. 8d. Mr. Harold W. Couzens has been appointed electrical engineer in charge at a salary of £120 per annum, to commence from January 1 last. The time for which Mr. Witham, jun., was taken as a pupil without salary has expired, and he will be paid £20 per annum, as an assistant, to commence from the 1st inst. A policy is to be taken out with the Boiler Insurance and Steam Power Company for £1,500 for the three boilers grouped, to cover all losses. Mrs. H. Howard has duly executed the indenture for the apprenticeship of her son, Archibald J. Howard, for a period of one year from October 1 last, and has paid the amount of the premium—viz., £50. Councillor Potter stated that the whole of the lighting on Good Friday and Easter Monday, when the shops were closed, was run from these new machines. Alderman Standfast thought the Electric Light Committee were drawing pretty near the end of their tether as regards expenditure of the loans. At present they had spent £12,635 out of the loan, and £1,638 by working expenses. Councillor Potter said the charge per lamp was just the same, and the increase in returns was due to the increase in the number of lamps and also in the number of hours. The working expenses thus far had been £1,495, and in that sum was included £133, which would not occur again, from small sundries taken over from the late company. The receipts were about £1,300.

Lighting Railway Tunnels.—Mr. Charles E. Parsons, of Newport, writes to the *Western Mail* as follows: "The plan at present adopted by most of our principal railway companies of lighting their carriages during the daytime with the old-fashioned and unsatisfactory oil lamps whenever the journey to be made includes one or more tunnels ought surely to give way to a cheaper, safer, and more effective system The cost of maintaining these lamps, which are burning to waste in daylight when the train is not running through a tunnel, must be far greater than the introduction of a simple system for electrically lighting the tunnels themselves by a switch arrangement, which could be operated upon by the engines turning the light on or off as they enter and leave the tunnels. An ordinary mechanical contrivance, such as a small switch level with the rail, could turn on the light on one side for the whole time any train (passenger, goods, or mineral) was passing through, and would have the great advantages of warning and of assisting all workmen or others in the tunnel to make themselves perfectly safe, instead of being obliged to run the terrible risks which are now of daily occurrence, and would also enable the engine-drivers to see their roads ahead. The turning-off switch might, in cases where tunnel repairs are being carried on, be disconnected, and thus a full and ample light be assured to the workmen, instead of the inadequate paraffin lamps and flambeaux now in use, while the turning-on switch could be disconnected at night when the carriages are fully lighted. Between Bristol and Cardiff there are three tunnels, and for a journey of one hour and a half the carriages are needlessly lighted for five-sixths of the day journeys. Many similar instances could, of course, be quoted."

Guildford.—At a meeting of the Urban Sanitary Authority last week the clerk submitted the following report of the result of an interview which the Mayor and himself had with the Board of Trade in reference to the application of a provisional order to enable a private company to supply the borough with the electric light: "We beg leave to report to the Council that in accordance with the instructions given at their meeting held on the 27th day of March last, we attended at the Board of Trade on the 31st day of March last at the meeting which had been appointed by the Board of Trade for the purpose of giving the Corporation and the promoters of the Guildford electric lighting order an opportunity of placing their views before the Department. After the representatives of the promoters had stated their case, relying greatly upon the provisions of the Electric Lighting Acts, as to the term of purchase being 42 years, we represented to the Board of Trade that the Town Council were of opinion that the electric lighting of the borough should be in the hands of the local authority, but that as the Council were not prepared to undertake the work at once, they had resolved to give their consent to the granting of the provisional order to the promoters only on the condition on which it had been given—namely, that the Council should be entitled to purchase the undertaking at the expiration of 10 years from the date of the order on the terms set forth in the second section of the Electric Lighting Act, 1888, and we also explained the circumstances under which, after such consent had been given, the Council had been advised by Mr. Phillips that the surplus water power at the Guildford Mills might with advantage be utilised in providing a supply of electric light in the borough. The representatives of the Board of Trade then enquired whether we were authorised to name a period within which the Corporation would undertake to carry out the work themselves, and on our stating that we were not authorised to give any undertaking which would bind the Corporation to carry out the work themselves within a definite period, the gentlemen representing the Board of Trade intimated that the Board of Trade would be advised under the circumstances to dispense with the consent of the local authority to the granting of the provisional order to the Holloway Electricity Supply Company, Limited, and added that the Board of Trade would be prepared to consider any representation that might be made to them by the Corporation for the insertion in the provisional order of clauses which would give the Corporation power to acquire the undertaking at some period before that fixed by the Electric Lighting Acts of 1888, provided that such representation were sent to the Board of Trade without delay." The Mayor said he thought they might, perhaps, try to get powers to purchase the undertaking in 30 years, but he did not believe they would ultimately do any good by any other proposition, and he had not a very hopeful view as to that one. Unless they could support their application on very strong grounds they could not derive very much benefit. The statute laid down 42 years, and if the local authority would not proceed to supply electricity he did not think the financial question between them and the company would be a matter in which the Board of Trade would take much trouble about. Alderman Allen did not think that they would be doing right to the ratepayers to allow a monopoly of the character proposed to come into the town for the long period of 42 years. He suggested that a committee should be appointed to consider the matter. The Mayor suggested that an application be made to the Board of Trade to reduce the term of years to 30. Alderman Allen moved that a request be made to the Board of Trade that a clause be inserted in the provisional order giving power to the Corporation to take over the undertaking on the statutory terms at the end of 30 years. Alderman J. Mason seconded the motion, but said that he did so as a matter of form, as he did not think it would do any good to them. The resolution was carried by seven to five.

Trades Union Question at Portsmouth.—The recent appointments made by the Electric Lighting Committee of the Portsmouth Town Council in connection with their new works are regarded with disfavour by local trades unionists, and particularly by the members of the Amalgamated Society of Engineers. The members of this society feel that the claims of the electricians among the ranks of their important trade organisation have not received the consideration to which they are entitled under the resolution adopted by the Corporation a short time since, adopting the principle of paying "the current rate of wages" to all workmen in the service of the municipal authority. The terms of the advertisement inviting applications for the appointments to be created by the installation of the electric light in the borough have been severely criticised by the local branches of the society, and with a view to bringing about a satisfactory readjustment of the matter, a deputation consisting of the president and two delegates, representing the District Committee, sought an interview last week with Alderman G. Ellis, and T. Scott Foster, chairman and vice-chairman of the Electric Lighting Committee respectively. The president observed that the organisation embraced electrical engineers, and fixed the minimum rate of pay for all members employed in this division at 36s. per week. Their present ground of complaint was that the remuneration offered by the Electric Lighting Committee to the mechanical engineers engaged for the new works was considerably below the current rate of wages. Alderman Ellis informed the deputation that the officials referred to were not mechanical engineers. He admitted that the advertisement was wrongly framed, and hence a misunderstanding had arisen. The gentlemen appointed by the committee should properly be described as "assistant superintendents." They probably had some knowledge of mechanical work, but were by no means trained to the use of tools like fitters who had served an apprenticeship to their trade. Nor were they required to do the work of a fitter. They would have to deal with no fewer than 13 dials and work out mathematical calculations, in order that the power might be properly given according to the varying requirements of the consumers. The Board of Trade insisted that scientific men should be employed upon such important duties, and he would not for a moment hold himself responsible for what might occur in the event of the work being placed in the hands of men who had not received that scientific education which could alone ensure their fitness for the work. Alderman Scott Foster pointed out that the three young gentlemen engaged as assistants under Mr. Price, the superintendent of the new works, occupied positions analogous to those of nearly all physicians, just qualified in the medical profession. They had been articled to electrical engineers, and having spent several years in the capacity of students, took up positions at nominal salaries under superintendents of important electrical works, with the object of gaining as much experience as possible, and thus qualifying for superior appointments. The President said that his society did not recognise them as electrical engineers, because in the opinion of the members they were being drafted into certain positions with the object of robbing them of the work which should belong to their trade alone. Two of the deputation were electricians who could design, construct, and work the whole of the committee's machinery. The men appointed might be able to make mathematical calculations, but the moment anything went wrong with the plant they would be compelled to fly to mechanics for the execution of the repairs. Was it right or just that men who could not be relied upon to set matters straight in case of emergency should be employed on work which properly belonged to fitters? Alderman Foster said that they were not there to argue that matter. The question at issue was, "Do these three men come under the rules of your society?" The committee had consulted eminent electrical engineers, who told them positively that it was necessary to have these scientific men at their works. Alderman Foster

Digitized by Google

repeated that the Amalgamated Society of Engineers had nothing to do with the three assistant-superintendents, who were in the same position as Mr. Price, with the exception that they did not receive so much remuneration. They wished to come there for further experience. A delegate complained that the advertisement relating to the appointments was not published in time to find its way into the electrical papers. Alderman Foster said that the committee issued no advertisement with regard to the appointment of mechanical engineers. They had promoted Mr. Randall and two others who had been working under him at the Town Hall. The Chairman said that the interview would be reported to the committee, and he had no doubt that the representations of the Amalgamated Society of Engineers would receive every consideration at the hands of the committee as long as they were confined to men belonging to the society.

PROVISIONAL PATENTS, 1894.

April 9.

7050. **Improvements in electrically-illuminated signs.** Guy Carey Fricker, 46, Lincoln's-inn-fields, London.

7054. **Improvements in electrically-propelled vehicles.** Ernest John Clubbe and Alfred William Southey, 53, Chancery-lane, London.

April 10.

7080. **Improvements in phonographs.** Joseph Oulton, 2, Market-street, Bradford.

7094. **Improvements in and connected with secondary electric batteries.** William Joseph Starkey Barber-Starkey, 70, Market-street, Manchester.

7116. **Apparatus for calling any desired station on a telegraphic or telephonic line.** Charles Bradbury, 249½, High Holborn, London. (Franz Trinks, Germany.) (Complete specification.)

7121. **Improvements in electric car lighting apparatus.** William Biddle and Patrick Kennedy, 33, Chancery-lane, London.

7145. **Improvements in or connected with the electro-deposition of metals or metallic compounds and the treatment of deposited metals or compounds.** Sherard Osborn Cowper-Coles and Baldwin Wake Walker, Bart., 47, Lincoln's-inn-fields, London.

7148. **Governor for electric, water, and other motors.** Nathaniel Shepard Keith, 24, Southampton-buildings, Chancery-lane, London.

7155. **An improved multiple distributing electric cut-out.** Albert Higgins, 48, Osnaburgh-street, Regent's Park, London.

7165. **Improvements in secondary voltaic batteries.** Ernest John Clubbe and Alfred William Southey, 53, Chancery-lane, London.

7176. **Improvements in and relating to telephonic systems.** Henri Carbonnelle, 45, Southampton-buildings, Chancery-lane, London.

April 11.

7205. **A new or improved process for the electro-deposition of aluminium and aluminium alloys.** Alfred Francis Bilderbeck Gomess, 24, Alfred-place West, South Kensington, London.

7206. **A new or improved process for the electro-deposition of aluminium and aluminium alloys.** Alfred Francis Bilderbeck Gomess, 24, Alfred-place West, South Kensington, London.

7214. **Improved safety arrangement for electric miners' lamps.** Howard Vivian Coad, 37, Cursitor-street, Chancery-lane, London.

7215. **Improvements in electric printing telegraphic apparatus.** Eugene Magnin, 65, Chancery-lane, London. (Complete specification.)

7216. **An improvement connected with electric switches.** Richard Hurst, 166, Fleet-street, London.

7238. **Improvements in or relating to electric telephones.** Sir Charles Stewart Forbes, Bart., 45, Southampton-buildings, Chancery-lane, London.

7239. **Improvements in alternating-current electric motors.** Carl Coerper, 45, Southampton-buildings, Chancery-lane, London. (Complete specification.)

7244. **Improvements in apparatus for electrically recording circular, longitudinal, or transverse motions of mechanical devices.** William Hopkin Akester and Henry Hubert Price, Granville House, Arundel-street, Strand, London.

April 12.

7258. **Improvements in electric arc lamps.** Gustav Binswanger and Herbert John Coates, 71, Queen Victoria street, London.

7287. **A method of electrically lighting vehicles by their own momentum.** Stuart Robson, 210, Brixton-road, London.

7307. **A new or improved electrical appliance for sounding an alarm when any desired temperature is reached, also serving as a fire alarm.** Charles Balbiani, 22, Glasshouse-street, Regent-street, London. (Complete specification.)

7311. **Improvements relating to secondary batteries.** Bernar c Alfred Nicolas Dorez, 45, Southampton-buildings, Chancery-lane, London.

7322. **An improved electric central alarm or call apparatus.** Conrad Christgau, 1, Queen Victoria-street, London. (Complete specification.)

April 13.

7396. **An electric contact apparatus worked by railway trains.** Edward Tyer, 28, Southampton-buildings, Chancery-lane, London.

7402. **A new or improved gas or electric light regulating apparatus for railway stations.** Laurence Barnard Tappenden, 37, Chancery-lane, London.

April 14.

7467. **Improvements in primary electric or secondary batteries.** Augustus John Marquand and Emmanuel Hancock, 24, Southampton-buildings, Chancery-lane, London.

7468. **Improved method of and apparatus for distributing electrical energy by means of alternating currents.** Engelbert Arnold, 28, Southampton-buildings, Chancery-lane, London.

7477. **Improvements in apparatus and means for vulcanising small articles, more especially intended for vulcanising the insulation at the joints of electric conductors.** Henry Edmunds, 47, Lincoln's-inn-fields, London.

7479. **An improved electricity meter for registering the amount of current consumed on direct, or alternating, polyphase, triphase, or quadruplephase circuits.** Frederick John Beaumont and Frederick Hallows, 166, Fleet-street, London.

SPECIFICATIONS PUBLISHED.

1882.

1862. **Electrical railways or tramways.** Handford. (Edison.) (Second edition.)

1892.

9346. **Electrolysis of chlorine, etc.** Kelner. (Second edition.)

1893.

6233. **Electric clocks.** Du Bois.

6306 **Electric current meter.** Nielsen.

6780. **Secondary batteries.** Doubleday and Sussmann.

9641. **Signal for telephone circuits.** Hall and Pickernell.

10015. **Utilising electrical energy for culinary purposes.** Crompton and Dowsing.

24864. **Dynamo-electric machines.** Thomson.

1894.

3273. **Arc lamps.** Chester and Rathbone.

3730. **Electric arc lamps.** Claremont.

NOTES.

The Latest Diversion.—Gambling through the telephone.

Siam.—The electric tramway at Bangkok is being extended.

Limoges.—This town will shortly be lighted by electricity.

The Antwerp Exhibition.—This exhibition is to be opened on the 5th proximo.

The Cance Arc Lamp.—Various improvements have been effected in the Cance arc lamp.

Camberwell.—Mr. Morgan declares that Peckham can be lighted by electricity without touching the rates.

Kaiserslautern.—A site has now been decided upon by the municipal authorities for the central electric light station.

Search-Lights.—On Monday, at Swansea, Mr. John S. Brown demonstrated to a number of people the capabilities of a powerful search-light.

Edinburgh.—New telegraphic and telephonic apparatus is being installed in the new part of the building of the Edinburgh General Post Office.

Electric Illumination.—The concluding lecture on this subject was delivered by Prof. J. A. Fleming before the Royal Institution on Tuesday.

Athletics.—The Electric Athletic Association, in connection with the Central Telegraph Office, held a conversazione at the Holborn Town Hall last week.

The Late Frankfort Exhibition.—The long-delayed report of the Testing Committee of the Electrical Exhibition held at Frankfort on-the Maine in 1891 has now been issued.

Newport Tramways.—The Newport Town Council decided on Tuesday to purchase the local tramways. It is to be hoped that the Municipality will adopt electric traction.

Paris Electrical Testing Laboratory.—A table of the rates charged for testing different instruments appears in the current issue of the *Bulletin International de l'Electricité.*

Paris.—The engineering works of M. de Méritens, in the Rue Boursault, Paris, are about to pass into the possession of M. Saillard, who will supply electric light in several adjoining streets.

A Freight Railway.—The Common Council of New Haven, Conn., have decided in favour of an electric freight railway to traverse the city streets and carry freight to manufacturing establishments.

Crystal Palace School of Engineering.—Sir Edward H. Carbutt presented on Saturday the certificates gained by students of the Crystal Palace School of Engineering during the Easter term.

Lighting of Mines.—A paper dealing with the electric lighting of mines was read last week by Mr. F. Brown before the South Staffordshire branch of the National Association of Colliery Managers.

The Telephone Supersedes the "Tickers."—The removal of "tickers" from the offices of outside brokers has led to the substitution of the telephone between in one case a member of the Exchange and a bucket shop.

Telephony.—An extension of the telephone system is to be made from Weston-super-Mare to Bridgwater and Taunton. Telephonic communication has just been established on the railway between Crieff and Comrie.

The Fleecing of Inventors.—We are glad to see that the *Pall Mall Gazette* has now started a crusade against the swindling policy pursued by some patent agents. Let the scroll be unrolled and show prominently how inventors are fleeced.

Tuscany.—Two concessions for the introduction of the electric light in Pratovecchio and Stia have been granted by the local authorities to Mr. Nardi. The alternating-current system is to be adopted, and alternators of Italian design will be used.

Telephony in Christiania.—According to the annual report of the Christiania Telephone Company, the number of subscribers at the end of 1893 was 3,774 with 4,235 instruments, as compared with 3,287 and 3,620 respectively at the end of the preceding year.

Report on the Hermite System.—Copies of the report on the experiments made with the Hermite system at Brest, and to which reference was made in our last issue, may be obtained of Messrs. E. and F. N. Spon, 125, Strand, W.C., at the price of sixpence each.

Royal Institution.—On Thursday next, the 3rd prox., Prof. Dewar will deliver the first part of a course of lectures at the Royal Institution on "The Solid and Liquid States of Matter," and on Saturday, May 5, Captain Abney will begin a course of lectures on "Colour Vision."

Lighting of Railway Stations.—The electric lighting of railway stations in Prussia has made good progress. The total number of lamps at such installations amounts now to 2,772 arc lamps and 11,261 incandescent lamps. Most of these stations have their own plant.

Milan.—The Società Generale di Elettricità had 33,080 incandescent lamps connected to their mains in December last, as compared with 25,490 in the corresponding period of the previous year. In addition to these, the company supply the current for working the electric tramway.

Electrical Trades Section.—A meeting of the Electrical Trades Section of the London Chamber of Commerce will be held at Botolph House, Eastcheap, on Friday next, the 4th May, at 2.30 p.m., to consider the Locomotive Acts in relation to the traction industry.

The Glasgow Central Station.—The current number of the *Transactions* of the Institution of Engineers and Shipbuilders contains, among other information, the paper read recently before that institution by Mr. Wm. Arnot, A.M.I.C.E., on "The Corporation Electric Light Supply."

Lyons.—A proposal has been submitted to the exhibition authorities by M. Claret for the electric lighting of the grounds and the Grand Cupola on condition of being allowed to issue tickets for admission to the Cupola and the Palais des Beaux Arts. The matter is under consideration.

James Forrest Lecture.—The council of the Institution of Civil Engineers announce that on Thursday next, May 3rd, the second lecture of the James Forrest series will be delivered by Dr. John Hopkinson, F.R.S., M.I.C.E., whose subject is "The Relation of Mathematics to Engineering."

French Union of Electrical Workers.—The Chambre Syndicale des Ouvriers Electriciens is making efforts to get all the electrical workmen to join its ranks. A register of vacancies is kept, and among other objects is the keeping up of the standard of wages and the insurance against accidents.

Electrical Communication with Lightships.—Earl Spencer, speaking the other day, remarked, in con-

Digitized by Google

nection with the recent report of the Royal Commission on this subject, that they might hope soon there would not be a single spot on the coast where such communication had not been effected.

Students of the Institution.—A students' meeting of the Institution of Electrical Engineers will be held on Friday next, the 4th May, at 28, Victoria-street, S.W. Mr. F. Digby Latimer will read a paper, entitled "A Description of the Electrical Type-printing Instruments as used by the Exchange Telegraph Company."

Coxeyites on the Cars.—The Coxeyites, the labour army of Mr. Coxey, captured a number of electric cars south of Omaha a few days ago. So runs a Press message from New York. The telegram does not state whether they caught anything else, as, for instance, a shock sufficient to knock them into a cocked hat.

A Large Electric Railway Scheme.—An article of incorporation has been filed for the Central Jersey Traction Company, which is to develop the electrical scheme devised by Joseph H. Realls, of New York, who expects to connect New York and Philadelphia and all the intermediate points by a trolley system.

Milan.—Messrs. G. Robecchi, de Zeme Lomellina, and Mario Azari have drawn up a scheme for the electric transmission of power to Milan. The power available in the Toce Valley from two waterfalls amounts to 57,000 h.p. Of this, it is proposed to transmit 22,500 h.p. to Milan. The total cost is estimated at £640,000.

Prompt Statistics!—The United States census department have now issued figures relating to the electrical industries in the State of New York They are based on returns made for the year ended May 31, 1890, and are of course of no value whatever in throwing light upon existing circumstances in the electrical trades.

City of London.—The returns published in another column show the progress which the City of London Electric Lighting Company is making. A noteworthy feature in this connection is the fact that the company intend in future to publish similar returns every quarter, an example which might well be followed by other supply companies.

The South Staffordshire Tramways Action.—A satisfactory conclusion to this action, which was detailed in our last issue, and the decision of which we give this week, has been arrived at. The conclusion is the issue of a *stet processus*. Those who do not understand this phrase will find the definition of it in ——'s dictionary. It means ——.

Destructive Effect of Electrical Currents on Subterranean Metal Pipes.—We have received an advance copy of a paper on this subject by Mr. Isaiah H. Farnham, which was to be read at a meeting of the American Institute of Electrical Engineers. The question is a very important one, and we hope to reproduce the paper in an early issue.

The Eight Hours' Day.—A pamphlet on "The Eight Hours' Day in British Engineering Industries," by Mr. J. Stephen Jeans, has just been published by Messrs. Ballantyne, Hanson, and Co., of Tavistock-street, W.C. The *brochure* has special reference to the recent report of Messrs. Mather and Platt, some of the details of which were given in a previous issue.

Protection of Workmen Against Accidents.—A new law is about to be set in operation in France for the protection of workmen against accidents. With regard to steam, gas, electric, and hydraulic motors, it is stipulated that they shall only be accessible to those persons who have to attend to them, and that the starting and stopping of any motor must always be preceded by a signal previously agreed upon.

Visit to University College.—This (Friday) evening, at 7.30 p.m., the members of the Junior Engineering Society will visit the new mechanical and electrical engineering laboratories at University College, Gower-street, W.C. The visitors will be under the guidance of Prof. T. Hudson Beare and Prof. A. J. Fleming, who have arranged special demonstrations in connection with the various machines.

A Railway up the Jungfrau.—Another scheme for the construction of an electric railway to the summit of the Jungfrau has been laid before the Berne Conseil d'Etat, the projector this time being Mr. Guzer Zeller, of Zurich. Starting from Scheidegg, the highest point of the Wengeralp railway, the line is to ascend to the Eiger Glacier, the Eiger, and the Mönch. The summit of the Jungfrau will be reached by an elevator.

Lighting of the Baltic Canal.—It is intended to light by electricity the Baltic Canal, by means of 25,000 incandescent lamps arranged on the two banks of the canal. Each lock will, in addition, be illuminated by 12 arc lamps, and electric lamps will also be used for signalling purposes. This installation is to be set in operation next year. The generating plant will be placed in buildings constructed at Holtenau and at Brunsbüttel.

Storage Batteries.—In a paper on "Central-Station Lighting," which has been read by Mr. Pedro G. Salom before the Franklin Institute, he advocates the employment of storage batteries in central-station lighting on the grounds that they effect a substantial saving in operating expenses; that they increase the factor of safety; and that they permit of a material extension of distribution without increasing the size of the power plant.

"Clay Pigeons" and Electrics.—We fail to see any connection between "clay pigeons" and electrics; but the Herculite and Electrical Manufacturing Company, Limited, of Bower-road, Hackney Wick, evidently know the difference. The company has been mulcted to the extent of 20s. fine and £5. 5s. costs for selling as "clay pigeons" pigeons made of a bituminous composition. We would suggest that the company should shoot the "clay pigeons" and keep the electrics alive.

O.S.A. Smoking Concert.—A smoking concert of the Old Students of the City and Guilds of London Institute will take place on Friday next, May 4, at Mason's Hall Tavern, Mason's-avenue, Basinghall-street. Mr. T. E. Gatehouse will play the violin, Mr. Thos. H. Harrison will sing, and many other able performers have promised to assist. It is to be hoped, as it is some time since the last social meeting of this kind was held, that the members of the O.S.A. will gather in large numbers.

Lectures.—The sixth of the series of lectures arranged by the executive of the Wigan and District Mining and Technical School was delivered last week by Mr. G. S. Corlett, A.M.I.E.E., on "The Application of Electricity to Mining Operations." The last lecture of the course on "Electrical Engineering" was given on Monday at the Central Higher School, Sheffield, by Mr. T. Scott Anderson. The lecturer clearly described the various methods of electric welding and their chief applications.

Society of Arts.—On Monday, at 8 p.m., the first Cantor lecture on "Typewriting Machines," by Mr. H. C. Jenkins, A.M.I.C.E., will be delivered. The lecture will deal with writing and printing machines, machines at the 1851 Exhibition for the use of the blind, elementary forms of typewriters, and early attempts to construct practical machines by Hughes, Wheatstone, Foucault, Beach, and

Digitized by Google

others. On Wednesday, at 8 p.m., a paper on "Nickel," by Mr. A. G. Charleton, A.R.S.M., will be read.

The Explosion at Nantes.—With regard to the recent explosion at Nantes, referred to in our issue of the 6th inst., a French contemporary states that this incident again shows the necessity of some control being exercised over installations in course of being carried out and during the working of stations. The question of a municipal control in Paris has been recently discussed, and the journal in question asks whether fresh accidents are to be awaited before some such organisation is constituted.

Frankfort-on-the-Maine.—Good progress is being made with the municipal central electric light station. The machinery house is to be completed by the end of June. It is hoped that the installation will be at work on the anniversary of the day when the local authorities authorised the project, which will fall on October 12 of the present year. For the first lighting section which is to be taken in hand, applications have been received equivalent to 25,000 lamps. They include a number of applications for motors.

The Clontarf Electric Tramway.—At a recent meeting of the Commissioners, held in the new Town Hall, Clontarf, Mr. Antony O'Connor and Mr. S. G. Frazer appeared as a deputation to seek the Commissioners' sanction to a proposed electric tramway between Clontarf and the Hill of Howth, to be laid down by the Clontarf and Hill of Howth Tramway Company, Limited. The secretary has been instructed to communicate with Lord Ardelaun, as the proposed tramway would go over his property.

Electrical Exhibition in Paris.—It is proposed to hold an electrical exhibition in Paris next year from July 1 to October 31, using for the purpose the machinery hall at the Champ-de-Mars and the Palace of Industry at the Champs-Elysées. In the former there are to be installed steam-engines and dynamos for the transmission of power, while the latter will be devoted to electromotors and all applications of electricity. The two buildings are to be connected by electric tramways, where different systems of electric traction will be shown. Electric boats will also run on the Seine.

South Africa.—A congress of the chambers of commerce throughout the whole of South Africa sitting at Cape Town has passed a resolution advocating a reduction in the cable rates to Great Britain. Mr. Jagger, the mover of the resolution, said that the Eastern Telegraph Company derived £120,000 a year from South Africa, and that they could reduce their charges and yet leave themselves a handsome profit. It was resolved that the subsidies ought to be rearranged, so that all the South African Governments might join in them, and might renew their contracts on a basis of reduced charges.

The Chemnitz Station.—The first scheme for the central electric light station which is being erected here by Messrs. Siemens and Halske, was arranged for 5,000 16-c.p. lamps in operation simultaneously, and the work was to be carried out so as to have mains laid down for the supply of 10,000 lamps. However, the demand has been so great that already, before the work has been completed, further powers have been asked for. Applications have been received for 8,750 incandescent lamps, 248 arc lamps, and electromotors to the extent of 194 h.p. The applications are equivalent to 13,250 16-c.p. lamps.

The "Electrical Review" v. Harness and others. Messrs. Alabaster, Gatehouse, and Kempt, the proprietors of the *Electrical Review*, have this week endeavoured to secure from Mr. Harness and others the costs, amounting to £596, incurred by them in defending, which they did successfully, the action brought by Dr. Tibbits against them. The action, which was heard before Mr. Justice Hawkins and a special jury in the Queen's Bench Division, was brought for "maintenance." After evidence had been given, the jury was discharged, and the case now stands over for legal argument as to whether "maintenance" could be made out upon the evidence offered.

Electrical Conductivity of Some Solutions of Salts.—Mr. A. C. MacGregory in the *Ann. Phys. Chem.* has determined the conductivities of solutions of calcium chloride, nitrate, sulphate, and acetate; strontium chloride, nitrate, and acetate; barium and silver acetates; and potassium oxalate. The results are given in tabular and curve form. The curves for the molecular conductivities are, in general, of a perfectly regular character, and show little tendency, even with the most dilute solutions, to a departure from their usually rectilineal character. Silver acetate shows, however, a change in curvature in dilute solutions, for which no cause can as yet be assigned.

The Beto Noire of Electric Supply Companies.—One of the bugbears of electric supply companies is the liability of actions being brought against them on account of vibration set up in buildings adjoining the generating stations. Several cases have already been before the Courts, and now, as recorded in our legal columns, the City of London Company have had their turn. It was hardly to be expected that such an unreasonable request as an injunction would be granted against a company working under statutory powers of this kind, and the plaintiffs are fortunate in being entitled to enquiries as to the damages caused, etc. At the same time, is there no effectual means that can be adopted to overcome vibration so as to remove this *bête noire* from our midst?

Self-Oiling and Filtering Pedestal.—A new self-oiling and filtering pedestal is being introduced by Messrs. Straker, Whitworth, and Co., of 139, Cannon-street, E.C. The appliance, which has been devised by Mr. Straker, is applicable to spindles and shafts rotating at from 150 to 10,000 revolutions a minute. The oiler is a continuous circulator, and is embodied in the design of machinery bearings. It can be attached to existing machinery or employed in the form of a self-contained pedestal. We are informed that these pedestals are being constructed under license by Messrs. Siemens Bros. and Co., the Electrical Construction Company, and other firms, for dynamos, motors, and shafting, and that a large number of them are already at work on other types of high-speed machinery. It is claimed that the pedestal will work efficiently for months without replenishing or requiring any attention.

Electric Bells.—We have received from the General Electric Company, Limited, 71, Queen Victoria-street, the tenth edition of their electric bell and general catalogue. Among the contents are descriptions of bells for houses, stables, mining, signalling, fire-alarm circuits, and various sets of bells, improvements in which have been made. Holden's repeaters for electric bells have been remodelled by the original inventor. A large variety of pushes is illustrated, including all-china pushes. A considerable amount of space is devoted to batteries, which are illustrated in all their different parts. Among them are the E.C.C. dry cells. Fans driven by Edison-Lalande cells are also detailed. Among electric gas-lighters there have been introduced, in addition to the usual form, a new type specially adapted for lighting gas-stoves, and also lighters with bent spires for window lights where inflammable articles are on show. As an appendix there are given a few notes on the application of electricity, instructions for fitting and connecting electric bells, and diagrams

Digitized by Google

showing the usual ways of connecting up electric bells, indicators, etc.

Lighting in Berlin.—A report of the Berliner Elektricitäts Werke gives figures of the working of the company up to June, 1893. The number of lamps 30-watt) increased from 272,000 to 325,000 in the past year. The following is a table of the consumption in kilowatt-hours since 1885 :

	Private lighting.	Street lighting.	Electric motors.
1885 (Aug. 13 to Dec. 31)...	38,150	—	—
1886	303,120	3,094	—
1887-8.....	715,920	6,282	—
1888-9.....	1,173,780	19,962	12,956
1889-90	2,511,000	21,666	69,591
1890-91	3,554,000	21,884	274,457
1891-92	4,831,440	21,708	186,611
1892-93	5,228,600	21,776	238,042

There are now 232 electromotors in use of a total of 785 h.p. The net profit on last year's working was £54,470.

Lighting of the Embankment.—The Highways Committee of the London County Council reported on Tuesday that the Council on the 10th inst. instructed them to consider the advisability of widening the footways of the Victoria-embankment by taking in a few feet of the carriageway on each side, in order to allow the electric light standards to be placed on the sides of the carriageway without interfering with the trees. With reference to this suggestion the committee pointed out that the footways are of great width, 20ft. on the river side and 16ft. on the other, and in order that the lamp standards might be clear of the trees the width of each of the footways would have to be increased by 8ft., and that of the carriageway correspondingly reduced from 64ft. to 48ft. Having regard to all the circumstances, they were of opinion that it was not advisable that the course indicated in the reference should be adopted. They understood that the Parks Committee had now under consideration a suggestion that some of the trees should be removed to facilitate of the proper growth of the remainder; and they thought it advisable that, until some decision should have been come to upon this suggestion, the further consideration of the question of the positions to be occupied by the lamp standards should be deferred.

Tramway Companies and Electric Traction.—Some time ago it was suggested to the Board of Trade that the regulations and recommendations of the Joint Committee as to the use of electric traction should apply both to past and future legislation. The Board of Trade replied that they were quite prepared to consider the advisability of bringing in a Bill for the purpose of making these regulations retrospective should it be shown there was a consensus of opinion that the tramway world wished that such should be done. The London Chamber of Commerce and the Tramways Institute issued circulars to every corporation and tramway company. The result of the replies showed a want of foresight amongst those responsible for the management of the tramways for the benefit of the shareholders. The tramway companies replied that as they did not contemplate electric traction at the moment, they did not see how the circular applied to them. The few answers received were forwarded to the Board of Trade and the reply was that they considered a sufficient consensus of opinion had not been given to justify them in promoting the Bill. The council of the institute urge the members to pledge themselves to assist in procuring from every tramway company an expressed desire that the Board of Trade will ask for such legislation as is sufficient to make these regulations retrospective in every Act, whether that company contemplate or not the adoption of electric traction now or in the future.

Lighting of Poplar.—A report has been presented to the Poplar District Board by Mr. W. H. Preece with reference to the electric lighting of the area under their jurisdiction. Mr. Preece is in favour of electric lighting being supplied by municipal authorities direct, chiefly on the ground of economy, and because lighting is essentially a part of the duty of a sanitary authority. He says that the City is lighted by a private company, and the user has to pay 8d. per supply unit as against 6d. in St. Pancras, where the energy is supplied by the local authority. He further points out that the Corporation have entered into a contract for 21 years to have electric light supplied to their tenants in their markets at the same price as they have hitherto paid for gas. The Commissioners of Sewers are paying the electric lighting company £27 per annum for each arc lamp, but if they had generated their own light and done the work themselves, it would not have cost them more than £17 per annum each arc lamp. From this and other circumstances he draws a conclusion that, as the proper illumination of the streets is the function of the local authority, the Poplar Board should erect their own machinery and supply the light, for which purpose they have obtained a provisional order. The report is being printed for circulation, and an important discussion is to take place when this has been done. It is estimated that a capital of £30,000 will be sufficient for the first requirements of the Poplar district.

The Connelly Motor.—We note the formation of the Tramway Motor Company, Limited, to work the Connelly gas or oil motor for tramway traction. The prospectus quotes the cost of haulage by the different systems used on the lines of the Birmingham Central Tramways Company, but it omits to state the cost per mile run with the Connelly motor. The company assert that their motors "supply the cheap and at the same time effective haulage so greatly needed, and so long desired by all those interested in tramway companies." It would be interesting to learn some definite figures on this point. If the average cost of horse traction is assumed to be 6d. per car mile run, what is that of the Connelly motor? Intending investors in the company should ascertain information on this matter, as unless the company can prove to tramway companies that by the adoption of the motor a saving will be effected over their existing methods, there will be no inducement for the latter to adopt the system. Moreover, the Connelly motor has been before the public for some years, and, as far as we know, no tramway company has taken it up. Apart from this, the company are closing the subscription lists before the investing public has an opportunity of seeing the opinions of the technical Press on the prospects of the system, and are relying upon the statements made by the daily papers, which are entirely incompetent to decide the question as to the capabilities of the motor. It must also be borne in mind that electric traction on the trolley system has been demonstrated to be the best and cheapest yet introduced, and as the Board of Trade has now paved the way for its development, this method should now take the lead in this country.

The Proposed Pacific Cable.—Public opinion in the Australian colonies in favour of the proposed Pacific cable is growing in strength. It is felt, a *Times* correspondent remarks, that sooner or later the cable will have to be constructed, possibly under conditions which may be less favourable to the colonies and Great Britain than the cable now proposed, which would only touch British territory and would be controlled by British influence. In this connection Mr. G. Seymour, M.I.C.E., writes to an evening

Digitized by Google

paper, giving figures which show that the existing lines with which, directly or indirectly, the Pacific cable would have to compete, are in receipt of subsidies and guarantees amounting to a total of £227,179 per annum. Thus it would appear that to place the Pacific cable project on the same footing as the existing companies, this project should in common fairness be aided by the Governments interested in it, and who have so heavily handicapped any scheme which might compete with the existing telegraph lines. From another source we learn from Ottawa that the prospects of the Inter-Colonial Conference to be held there in June are very encouraging. Already Victoria, Queensland, South Australia, and New Zealand have agreed to be represented. As to the mother country, Lord Rosebery's promise of Downing-street representation will be remembered. That the colonies mean business is seen from the fact that Victoria proposes to send a deputation of five gentlemen. When Sir Thomas M'Ilwraith, Mr. Reid, and Mr. Huddart have concluded their labours in London, and the conference has been held, everyone will hope that it will only remain for the orders to be given out for the trans-Pacific cable and the new steamships of the "Imperial" Line.

Comparative Experiments on the E.M.F. of the Clark Standard Cell.—Mr. K. Kahle details in the *Ann. Phys. Chem.* experiments made with the object of ascertaining the effects which change of form, purity of material, age, and temperature have on the E.M.F. of the Clark standard cell. The H-form devised by Lord Rayleigh, the form proposed by Feussner, and that adopted by the Board of Trade were compared with one another. The results show that the H-cell is far superior to the other two, both in the ease with which it can at any time be reproduced of constant E.M.F. and in the fact that impurities and disturbing influences have less effect on its constancy, so that the variation of its E.M.F. from the normal value can with little difficulty be reduced to 0·0001 volt. Greater changes than this were not observed in cells which were often compared with one another during the course of 1½ years. In the effect which temperature has on this cell, it is also to be placed before the others. The author finds that a knowledge of the temperature coefficients of the Feussner and Board of Trade cells is misleading, as the E.M.F. calculated by their means does not agree with that actually observed. On the other hand, as long as sudden changes of temperature are avoided, the value of the E.M.F. for the H-cell can be calculated for different temperatures to within 0·0001 volt, and even with sudden temperature changes to within 0·001 volt. The coefficient for temperatures between 10deg. and 30deg. was found to be $-0{\cdot}000814 - 0{\cdot}000007\ (t - 15)$. The constancy discovered in the E.M.F. of the above form of the Clark standard cell leads the author to propose its adoption for the purpose of defining the unit of E.M.F. He condemns the form of cell adopted by the Board of Trade as not sufficiently fulfilling the requirements of a standard.

Lubricants and their Use.—At the last meeting of the Junior Engineering Society, held at the Westminster Palace Hotel on 13th inst., a paper on "Lubricants, their Use, Testing, and Analysis," was read by Mr. W. F. E. Seymour, of Swindon. The necessity of efficient lubrication and importance of being able to judge the utility of various lubricants for different kinds of work was first pointed out. Lubricants might be classed into solids, semi-solids, and liquids. The composition of vegetable, land, animal, fish, and mineral oils was considered, and their proper applications referred to. The author next gave an extended account of the more important lubricants—tallow, rape, olive, and castor oils—and detailed the uses to which they were each best adapted. Of mechanical testing appliances, Ingram and Stapfer's oil-tester and Thurston's machine were illustrated, and the mode of working and of recording the results were shown. The suitability of a lubricant for any particular duty could be judged by its viscosity and specific gravity, in the determination of which various forms of instruments were employed. The principal viscounters used were Beverton, Redwood's, and Sackar's; these were described, and the process of working with them explained. Passing on to chemical analysis, the methods adopted for the determinations of free acid, drying properties, flashing point, mineral matter, congealing point, total fatty acids, mineral oil, or unsaponifiable matter, were given. An appendix to the paper was devoted to Maumené's test, Pontet's claidix test, Valenta's acetic acid test, Dalican's method for congealing-point of tallow, and Gray's flash-point apparatus. In illustration of the paper, specimens of the various oils were shown for examination, and there were also a number of instruments exhibited which had been lent by Messrs. Baird and Tatlock. The proceedings closed with the announcement of the ensuing meeting on May 11, when a paper on "Engineering Experience at Sea" will be read by Mr. J. Lane, chief engineer, and Mr. J. Hawthorn, extra chief engineer, M.I.Mar.E.

Chicago Exhibition Awards.—The Royal Commission have issued a list of the awards to English exhibitors as received from America. In many instances it appears to differ from the lists issued from time to time at Chicago as the awards were made by the judges. Many of the entries refer to exhibits which did not form part of the British section. Each award consists of a bronze medal and a diploma. All awards are of equal value. The medals and diplomas will be forwarded to the exhibitors as soon as they are received by the Royal Commission. It is not anticipated that they can be ready for issue for a long time to come. In "Department F, Machinery," under Group 69, motors and apparatus for the generation and transmission of power, hydraulic and pneumatic apparatus, the following are among the awards made: Messrs. Galloways, Limited, Manchester, engine; Messrs. Richard Hornsby and Sons, Limited, Grantham, oil-engine; Mr. David Joy, Westminster, model of the Joy valve gears; and Messrs. Willans and Robinson, Limited, Thames Ditton, Surrey, Willans compound central-valve engine and Siemens dynamo combined. In "Department G, Transportation," Messrs. John Brown and Co., Limited, Sheffield, have received an award for an exhibit which included electro-coated shafting for steam vessels. In "Department J, Electricity," the following awards have been made: Group 123.—Apparatus for electrical measurements: Mr. James White, Glasgow, electromagnetic balances, "Kelvin." Group 124.—Electrical batteries, primary and secondary: The Epstein Electric Accumulator Company, Limited, London, storage batteries. Group 126.—Transmission and regulation of the electrical current: General Electric Company, Limited, high-insulation switches, and other incandescent house fittings. Group 133.—Electric telegraph and electric signals: British Government Postal Telegraph Department, London, collection of modern telegraphic apparatus. Group 137.—History and statistics of electrical invention: British Government, Postal Telegraph Department, London, historical telegraphic apparatus; Corporation of Birmingham, Birmingham, original Woolwich dynamo; and Group 138.—Progress and development in electrical science and construction, as illustrated by drawings and models of various countries: General Electric Company, Limited, London, carbons for arc lamps.

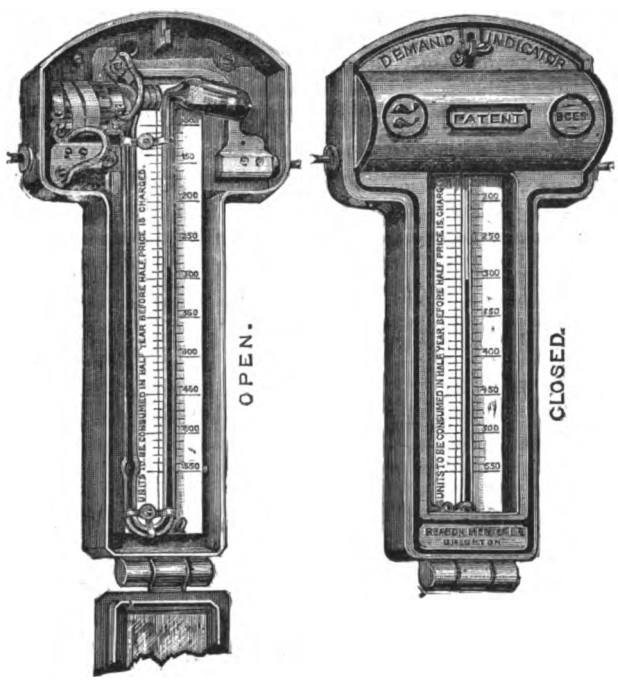
Digitized by Google

ELECTRICITY METERS.*

BY R. P. WILSON.

(Concluded from page 457.)

In conclusion, the most important and least appreciated meter at present on the market has been invented by Mr. Arthur Wright, of Brighton—viz., the maximum demand meter. A supply of electricity is not similar to a supply of gas, for the reason that the latter may be always produced under the most favourable conditions, whereas in the case of the electric light the maximum output required at any given time is a measure of the plant required in the central station. In view of the fact that electric light companies are not philanthropic institutions, it is evident that the most important duty of a central-station engineer is to make a profit. This can only be done by encouraging such customers as have a large consumption and a small number of lamps. Very many systems have been introduced from time to time to popularise the use of electricity, but the only one which produces the desirable customer is the method adopted by Mr. Wright—*i.e.*, to encourage a large consumption and diminish the maximum demand at any one time. This he has succeeded in doing by his method of charging at Brighton, which is as follows: The "maximum demand" meter is fixed in each customer's



Wright's Maximum Demand Meter.

premises, and registers the total amperes required at any one time during the quarter. After a certain number of watts have been used during the quarter (corresponding to this maximum demand, for two hours a day) all further current supplied is charged at half price, so that consumers have every inducement to increase their consumption by putting lamps all over the house, and they also have every inducement to minimise the number of lights turned on at any one time. As Mr. Magden points out, a customer having 10 lamps burning 10 hours a day only requires plant for 10 lamps that burn the same amount of light as a man who has 100 lamps which he burns for one hour, whereas the man with the 100 lamps requires 10 times as much plant and to all intents and purposes the same standing charges.

The meter itself consists of a U-shaped tube filled with a suitable liquid having a bulb at each end, one of which is surrounded by a coil in series with the ordinary meter, the other being bent down to form a trap. The current passing through the series coil heats, and therefore expands the air contained in the bulb it surrounds, and forces the liquid into the bulb at the other end; the quantity of liquid thus caused to overflow diminishes the height of the liquid standing in the right-hand tube, and thus gives a registration of the maximum demand this particular customer has made on the plant at the station during the quarter.

The following are examples of scales showing different methods of benefiting long-hour consumers, and thus encouraging profitable business. The first is the Brighton scale, and its great simplicity will at once be apparent. Current is supplied at 115 volts.

Maximum demand. Amperes. Instrument tube holding registering fluid.	Number of units to be consumed in half-year at 7d. All surplus at 3½d.
1	= 42 units.
2	= 84 units.
3	= 126 units.
4	= 168 units.
5	= 210 units.
6	= 252 units.
7	= 294 units.
8	= 336 units.
9	= 378 units.
10	= 420 units.

Example.—A customer's consumption in the half-year amounts to, say, 564 units, his indicated demand being eight amperes. He will then pay as follows:

336 units at 7d. =	£9	16	0
228 units at 3½d. =	3	6	6
564	£13	2	6

The next is a scale that has been tabulated for a company that has hitherto given discount proportional to the amount of the account, regardless of the actual maximum number of lamps in use at any time. Should the customer's consumption at the indicated demand not reach the figures in the first column, he is charged full price. Should the consumption exceed the figures in the first column, but not exceed those of the second column, he is to receive 5 per cent. discount off his account. Should this consumption range between the second and third columns, he receives 10 per cent. discount; if between the third and fourth, 15 per cent., and so on.

The basis of the different discounts is as follows:

5 per cent. when consumption equals customer's maximum demand for 700 hours in the year.
10 " " " 1,000 " "
15 " " " 1,200 " "
20 " " " 1,500 " "
25 " " " 1,800 " "
Voltage, 110.

Maximum demand. Amperes. Instrument tube holding registering fluid.	Discounts. 5%	10%	15%	20%	25%
	When following minimum quantities are consumed.				
1	77	110	132	165	198
2	154	220	264	330	396
3	231	330	396	495	594
4	308	440	528	660	792
5	385	550	660	825	990

Example.—If a customer consumes in the whole year 960 units at a maximum demand of five amperes, he is entitled to a discount of 20 per cent., which, at 8d. per unit, works out as follows:

960 units at 8d.	£32	0	0
20 per cent. discount	6	8	0
	£25	12	0

The discount for the year is in this case deducted from the customer's bill at Christmas, that being the darkest quarter, and also ending the financial year. The scale of discounts last given may be modified so as to offer a rapidly-rising bounty to long-hour consumers especially, but considerations of space will not now admit a fuller reference to this arrangement. The same reasons have curtailed the scales here described, but obviously they may be extended as desired. One thing of exceeding importance has been demonstrated—viz., that reductions in price on the basis of the foregoing scales will induce customers to wire their buildings more thoroughly, thus giving the works a long and profitable load, while the consumer obtains current at a sufficiently moderate price to efficiently compete with gas. Where motors are used, the instrument is equally useful, as the customer reaps the benefit of a long-hour load by getting a liberal discount off his whole bill.

There are, of course, very many other features in the meters referred to in this paper that deserve notice, but

* Paper read before the Northern Society of Electrical Engineers, April 9, 1894.

Digitized by Google

the limited time available has of necessity rendered this paper very incomplete. The author hopes, however, that it possesses some points of interest to members of this society.

DISCUSSION.

Mr. Wordingham: Mr. Wilson referred to a maximum demand meter of Mr. Wright. A thing of that kind is wanted. We certainly want it in this city, where we have a special method of charging. We charge now by the number of lamps connected. There is another maximum demand meter. It is made by Messrs. Nalder Bros., and is simply an ampere-meter with a horizontal needle, which pushes forward an aluminium pointer. I understand there is a certain amount of drop in voltage in Mr. Wright's meter. I should like to know what the drop is if Mr. Wilson can tell me. In the Chamberlain-Hookham meter Mr. Wilson mentions a very ingenious device for reducing the friction of the rotating disc. It certainly is ingenious, but it was invented by Ferranti. Mr. Wilson mentioned the Thomson meter. He says it has been used for five wires. There have not been very many made, I understand. We have one working here. It has been working for about five months. I have not any means of testing it, but judging from the weekly readings and the estimated consumption, it seems to be going very well indeed. Another point mentioned by Mr. Wilson with regard to the Thomson meters was that they now allow the shunt current to go through the main coil, whereas in the earlier instruments they had a subsidiary coil. The shunt winding and the armature together form a motor independent of the current through the lamps—the object being to overcome the initial friction. If the pressure rises above the normal, this may be more than just compensated for, and the meter will go without any current. There is one point worth mentioning. In testing watt-hour meters, you must either cheat the consumer or the company. Of course, what the consumer should pay for is the current through his lamps multiplied by the pressure at the lamps. Now, if the shunt winding be connected on the main side of the meter, the company is supplying a higher pressure than they get paid for. If, on the other hand, the shunt winding is connected to the consumer's side of the meter, the consumer pays for the current used in the shunt coil of the meter, which is, of course, no benefit to him. In the picture of the five-wire the current only reverses on the three inners, never on the two outers.

Mr. F. F. Bennett: It would have been interesting if Mr. Wilson had mentioned the amount of current passing through the shunt of the Thomson and other meters. Some time ago I made a test of the different shunt meters—viz., the Frager, Thomson, Reckenzaun, etc.—and I found the average current absorbed equal to about 10 milliamperes. If there were 1,000 such meters installed in a town, the current absorbed by the shunt would be equal to one Board of Trade unit per hour, and as there are 8,736 hours in the year, that number of Board of Trade units would be wasted, the total exceeding 11,000 electrical horse-power hours. This I consider a very substantial objection to the shunt meters. In the case of connecting a shunt meter up so that the meter would register the amount of current passing through, as has been suggested, it would be rather unpleasant for a consumer who went away for three months, and on his return found that a bill was charged against him, but knowing all the time that a single light had not been used during that period. It would be lowering the electric meter to the level of the gas-meter, which, to say the least, would be degrading to the former. Mr. Wilson made reference to Aron meters; I have had rather considerable experience with this meter, and I cannot say it is satisfactory. There are several objections: its fine clockwork and frail delicate outer case make it thoroughly unsuitable for a wet or damp cellar; the necessity of winding the two clocks up every month, and if one clock were to stop all record was lost; and it is a matter of a consumer owing the company a large bill, or the company owing the consumer, depending entirely upon which clock stopped. Another difficulty is the matter of adjustment or synchronising, and even when you have taken trouble daily for four or five weeks in the test-room to get a nice adjustment, on removing the pendulums, so that the meter may be transferred to the consumer's premises, it was often found that further labour in synchronising was required. In Preston a consumer objected to pay his bill, stating that his meter, which was an Aron, was registering when no lights were being used (he had listened and heard the clocks going). To convince the consumer that the meter was correct, I put in a Ferranti meter to check it, and there was not a 5 per cent. difference in the registration at the end of the month. The solicitor for the consumer, when I told him of this, said it was like "setting a thief to catch a thief," but I am glad to say the company got the verdict. The Ferranti meter is not without its faults. On several occasions I have found that it would not start with only an 8-c.p. lamp in circuit, and in some cases would not start where a single 16-c.p. lamp was only in circuit. I have made a careful test of all the meters, and I must say, without prejudice, that for compactness, accuracy, durability, and imperviousness to damp or wet, the Ferranti meter certainly takes first place.

Mr. Madgen: The order in which the various types of meters are placed to represent the extent to which they are respectively in use, may give rise to misconception. It is all very well as a matter of historical interest, but the point of commercial interest is the meters which are being put in to-day. Mr. Wilson wished to avoid the historical element, but we find him giving first place to the Aron meter—a form which is not now being fixed in any number to speak of. The Thomson-Houston meter, indeed, which he places second on the list, is, I believe, more in favour, but its wasteful shunt circuit is considered a drawback to its extensive use. The Shallenberger meter has undoubtedly been very extensively used, but it cannot be said that there is any finality in a meter which has only a range of about 35. In almost any town you will find several consumers—and the number is increasing—who have one or two lamps continually burning on landings, staircases, etc. A meter with such a limited range does not register such small consumption, which in the aggregate may amount to a very appreciable percentage of the revenue. The Ferranti meter has stood the test of time, and they are now being put in at the rate of about 500 per month, which is, perhaps, the best practical evidence in regard to them. They are neatly, but very strongly, made, so as to fit them for the trying situations in which meters are frequently placed. It is interesting to note, as Mr. Wilson points out, that these meters were the first provided with the double sealing arrangement suggested by the Board of Trade, but previously adopted (and I may add patented) by Mr. Ferranti. I am very glad that Mr. Wilson has so fully appreciated the advantage of Mr. Arthur Wright's demand indicator. The effect of his method of charging for current has shown itself in the results obtained in Brighton during the past year. The load factor improved to 15 per cent., the consumption per lamp fixed had increased, and customers are now being added at the rate of 10 to 15 per week.

Mr. Wilson, in reply, said: In reference to Mr. Wordingham's remarks, I have not seen the maximum demand meter manufactured by Messrs. Nalder Bros., but it is apparently the outcome of the principles evolved by Mr. Wright; but cannot, of course, form an opinion as I have never seen it. His question about the drop in the series coil of Wright's meter I cannot answer, because I do not know what it is. We may, however, assume that it is very small, as Mr. Wright is fully alive to the importance of making it as small as possible, and he undoubtedly knows as much about the subject as we do. With reference to the drop in the series coil of other meters, I think Mr. Wordingham attaches too much importance to this point, as it is in almost all cases so small as to be almost negligible. Mr. Wordingham states that the floating disc which is used in the Chamberlain and Hookham meter was invented by Mr. Ferranti. I had already made the same statement in the course of my paper, although apparently I did not make myself clear. In reference to the Thomson meter, Mr. Wordingham objects to the subsidiary or compounding coil in series with the shunt. Personally, I am at loss to see what objection there can be to this coil. It has not been done away with, as Mr. Wordingham suggests; on the contrary, it is now introduced even into the 5 and 10 ampere meters. In regard to the consumption of the shunt, it has been asked whether this should be paid for by the undertakers or the consumer. It is, of course, apparent that the company must in all cases lose this, as the Board of Trade would never allow the consumer to be charged with it, even assuming the consumer would consent to pay it if they did. Further, the shunt current is used for a specific purpose of overcoming initial friction in any meter. In doing so all its energy is absorbed, and therefore cannot communicate itself to the dials. That the shunt current costs money is important, but the value of any particular meter or meters may be readily ascertained by putting any number of different types that have been tested and found to be accurate in series. The best meter is the one that gives the largest revenue. There is no doubt that those manufacturers who use shunts in their meter are quite alive to the objections raised against them, but they are of opinion that this same shunt has advantages which more than compensate for the annual consumption they involve. Mr. Bennett appears to have been very unfortunate in his experience with Aron meters. There is no doubt foundation for his complaint that they do not invariably synchronise. I have the electric light in my office, and at first, when I went away, I always found I had a bill to pay when I came back, whether I had taken the precaution of taking out the fuses or not. The meter I have now does not do that, and it therefore follows that other meters can be made to behave themselves equally well. The meter, however, does undoubtedly require careful adjustment, but it is nothing more than can be done by a good watchmaker. With reference to Mr. Madgen's remarks, I am sorry to say that his statement to the effect that the resistance of the Thomson shunt is 1,000 ohms is not correct: it is, as a matter of fact, 3,000 ohms. Mr. Madgen has taken exception to the order of importance. I would remind him that the statement referred to is to the effect that the order in which these meters are placed represents approximately the extent to which they are being used (not put in). One of Mr. Ferranti's other representatives agreed with me that this order was correct, and it was not until he had acquiesced that I left it in the paper as it was. In reference to the Shallenberger meter having a range of 1 in 35, I am glad to be able to say that this has been improved, and they now claim to have a range of 1 in 80. The Westinghouse Company are, however, willing to admit that they do not make large meters on this principle, and do not pretend to. The only other point that was raised was about the meter supposed to have been exhibited at the Health Exhibition by Lord Kelvin, but this statement I corrected in reading the paper.

Ship-Lighting.—The new screw ss. "Tantillon Castle," the latest addition to the fleet of the Castle Line, was the first vessel to enter the newly extended graving dock at Blackwall. The steamer is fitted with a complete installation for electric lighting, the current being generated by three dynamos driven by independent engines.

INSTITUTION OF ELECTRICAL ENGINEERS, Apr. 26.

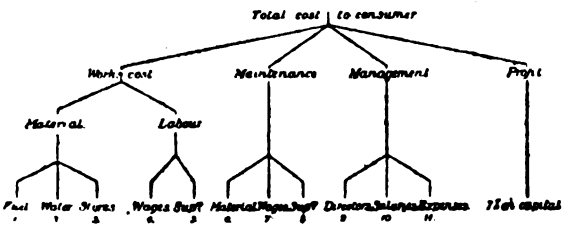
COST OF ELECTRICAL ENERGY.

BY R. E. CROMPTON, M.I.C.E., VICE PRESIDENT.

I address this paper to all who are interested in electrical supply, but especially to the engineers who design and who work electrical supply plant. It is almost exactly six years since I read a paper before this Institution* on this subject, and three years since I read a similar paper before the Institution of Civil Engineers.† I should be glad if those who are really interested in the subject would find time to glance over these two papers after reading the present one, as there is much contained in them which might have been repeated here with advantage if I had not feared to unduly lengthen the paper.

For convenience and brevity I use the word "works" for the whole plant of an electric supply company; such works may have several generating stations. I use throughout the word "energy" for the electrical energy, and I speak of the two well-known systems of distribution as "direct" or "converted" systems. By direct systems I mean all two, three, or other multiple wire systems, with or without storage, in which the energy is supplied direct from the dynamos to the mains, and from the mains to the users without change of pressure. I include amongst converted systems all those in which the energy is either generated at a high pressure, or converted up to a high pressure for transmission through the mains, and afterwards converted to the lower pressure at which it is supplied to the users. In this paper I do not deal with works using water power, but solely with those in which the electrical energy is obtained from fuel. The total cost to the user may be grouped under four heads: works cost, maintenance, management, profit. These may be conveniently sub-divided into 12 sub-heads or divisions, as follows:

TABLE I.



Of these 12 heads I propose to deal at length with 1 to 8 only. The remaining heads of management and profit are outside the province of us engineers, except in one important particular, which is that the interest or profit to be paid on the capital employed is affected by the choice of system used, and by the skill of the designer of the works, so that it is necessary for us to deal with it. Let us assume that our ideal works are designed for the most economical production of 5,000,000 units of energy per annum distributed to users in a large town and under average conditions. We are now in a position to estimate with considerable accuracy that the capital required for the preliminary expenses, for obtaining the requisite parliamentary powers, and for the complete equipment of such works, will not exceed £500,000, or at the rate of 2s. per unit sold per annum. I have arrived at this figure after considerable study of the capital account of existing companies, and of works carried out by local authorities, and I find that it is nearly certain that several existing works will reach this figure as soon as their plant is completed to the scale intended, and worked to the full output; so that, if we consider that entirely new works could now be certainly carried out at a lower cost than that of any existing works, it will be seen that my estimate is on the safe side. Now I think that such works ought to be able to include in the total cost to the consumer such a sum as profit as will yield 7 per cent. per annum on the whole of the loan as well as subscribed capital. In the case of a local authority, a portion of this 7 per cent. would be applied to paying the interest and sinking fund on the original loan, and the remainder would be applied as a profit in the reduction of local burdens or in introducing local improvements; but in the case of a joint-stock company this capital of £500,000 might advantageously consist of £200,000 in ordinary shares, £100,000 in 6 per cent. preference stock, and £200,000 in 4 per cent. debenture stock, so that the average of 7 per cent. on the whole £500,000 might be divided up as follows:

4 per cent. on debenture stock	£8,000
6 per cent. on preference stock	6,000
10½ per cent. on ordinary stock	21,000
Total	£35,000

This sum of £35,000 is equal to a profit of 1·68d. per unit sold. The cost of managing such a company can also be dismissed in a few words. Under this heading it is convenient to group directors' fees, salaries of managing staff and office, meter readers, collectors, all stationery, law, and audit charges, rates, taxes, and insurance. If we take the practice of the best-managed works as a guide, we find that about £8,200 per annum is sufficient to cover all these charges for the largest output that has been yet obtained. It is evident that a sum of £9,000 a year would be an ample one for the management charge on the output of 5,000,000 units. This management charge therefore works out at 0·42 a unit.

You will see, then, that at the scale of working that we are now considering, which is at a scale of output certain to be reached within a year or two by a large number of works, the management and profit items, taken together, should amount to 2·1d. per unit. As I have said above, we engineers have nothing to say in controlling these figures. They are certain to be reached in course of a few years, as it is a mere question of output. The question which I now propose for your consideration is this: What chance have we of reducing the present works cost and maintenance cost included in the sub-heads 1 to 8 to such an extent that the energy may be sold to the public at, possibly, the low figure of 3d. per unit? I believe that Mr. Swinburne has stated that electrical energy, whenever the demand is continuous, such as for certain electrolytic or electrometallurgical processes, can be generated and distributed to short distances at a works and maintenance cost of ¼d. a unit. I believe Mr. Swinburne has good grounds for this estimate, if cheap fuel is available. But for our present purpose, which chiefly concerns the supply of electrical energy used largely for electric lighting, and to a minor degree for power, we cannot fix such a low figure for our ideal works and maintenance cost for the future. Mr. Swinburne's case and those which we are now considering differ so widely. We can hardly hope for many years to come to improve the load-factors of works for general supply much above 20. The average of the London stations is still a long way off this figure, and I fear that the extensions of the use of energy for power and purposes other than lighting are likely to go on for some years to come at a slow rate. At a load-factor of 20 you must remember that all maintenance charges work out nearly five times as great as they would be if the output was continuous. It is useless to put before you ideal figures which we cannot hope to approach. I propose, instead, to adopt figures which we may hope to reach at no distant period, and have, therefore, prepared those given on Table II., and I give reasons for fixing on them as I deal with each sub-head in turn.

TABLE II.—Ideal Standard Works Cost.

	Cost per unit sold.	d.	d.
Works cost—			
1.	Fuel—2·5lb. Welsh coal at 20s.	0·27	
2.	Water	0·01	
3.	Petty stores	0·02	
4.	Wages	0·10	
5.	Superintendence	0·10	
	Total works cost	——	0·5
Maintenance—			
6.	Material on repairs	0·20	
7.	Wages on repairs	0·15	
8.	Superintendence	0·05	
9.		——	0·4
10.	Management		0·42
11.			
12.	Profit		1·68
			3·00

Working expenses, 44 per cent. of receipts.

FUEL AND WATER.—DIVS. 1 AND 2.—FUEL.

I agree with Prof. Kennedy in the remarks that he made on my paper read before the Institution of Civil Engineers* that the importance of the cost of the fuel used on electrical energy supply works is not to be measured merely by the money spent on the fuel itself, but that it is to a certain extent a measure of the quantity of plant that must be employed, and so affects the cost of upkeep of the plant, and to some extent every cost item, except, perhaps, management and profit items. At a very early stage in the history of electrical supply works it was found that in practice the amount and cost of the fuel used differed very widely from the amount estimated from the known efficiency of the plant. In 1883 modern engine-builders were making engines and boilers using less than 2½lb. of good coal per indicated horse-power, and the mechanical efficiency of these engines was certainly not less than 85 per cent. At that time dynamos could be made of 85 per cent. efficiency. We all thought that our distribution losses should not exceed 15 per cent., so that, putting these figures together, we were justified in hoping that our fuel bill would not exceed 5½lb. of coal per unit sold. We soon, however, found that in practice we could not approach such a degree of economy, so that the opinions of practical engineers in charge of supply works rapidly veered round to the opposite extreme, and among these gentlemen, even in 1888, when I estimated that the figure which was then prevalent of about 24lb. of good Welsh coal used per unit sold might in the future be reduced to 5½lb., I met with much incredulity. At so late a date as that of my paper before the Institution of Civil Engineers in 1891,† Mr. Raworth, in the course of discussion, stated that to his knowledge from 19lb. to 22lb. of coal was commonly being used, and that he considered the figures I then gave—namely, 7·9lb. for the Kensington and 6·5lb. for St. James's stations, for the best months of the year—were so satisfactory that they opened up a prospect of a new era for shareholders in those companies. I am glad to say that since that date improvement has been very regular; during the past year we have several times seen recorded during the winter months—in which, of course, the economy of fuel is at its best—a fuel consumption under 5lb. of Welsh coal per unit sold; so that my forecast, made six years ago, has already been more than justified.

I have arrived at my new possible or ideal figure of 2½lb. of Welsh coal per unit sold in the following manner: I find that we can in London count on obtaining this coal having an average calorific value of 14,500 B.T.U. per pound. With proper arrangements for heating the feed water to nearly boiling point boilers can be obtained which will evaporate 12lb. of water at our working pressure of 150lb. I think that the losses due to irregular working and banking fires can be so minimised that 2½lb. may evaporate 25lb. of water into dry steam—not on tests only, but as shown on the monthly bills. Condensing steam-engines can and will be made for us using not more than 12lb. of steam at from three-quarters to full load, or 13lb. of steam at from half to three-quarters load per indicated horse-power per hour. To these engines dynamos can be coupled direct of such efficiency that the combination will not use more than 18½lb. to 20½lb. of steam per unit per hour, measured at the dynamo terminals at the corresponding loads, so that an average of 20lb. per unit generated may be counted on during the time that these engines are actually at work. This allows for 10 per cent. of the steam evaporated being condensed in the pipes, or used in feed pumps or other obscure sources of loss, and a further 10 per cent. for our distribution loss, in order to account for the 25lb. of water I require to be evaporated by the boilers. It appears to me that the most convenient method of discussing the problem of reaching these ideal figures is to consider in turn the fuel that we use and the boilers and other steam-producing apparatus, the engines for using the steam, the dynamos for generating the energy, and, finally, the means for distributing the energy to the users—in each case with a view of locating the losses that now take place, and considering the best means of minimising these losses as far as may be possible. In London the favourite fuel hitherto used in electric supply works has been Welsh coal of the best quality, as it has been found that the cost of the carriage of fuel forms such a large part of its total cost when delivered on to the works, that in most cases it pays best to use nothing but fuel of the highest calorific value. This value in the case of the best Welsh coal may be taken at 14,500 British thermal units; for, although values as high as 16,700 have been noted in the case of Nixon's and a few other Welsh coals, yet it is probable that these exceptional values are not attained on the average, even from coal from the very same seam. As our ideal figure of 2½lb. therefore contains 36,250 B.T.U., it will be convenient, for purposes of comparison, or for considering the use of other fuel, to point out that 2½lb. of Welsh coal is equal to 36¼ B.T.U. per watt-hour of the energy sold. Table V. gives the calorific values of various fuels, determined by Bryan Donkin and Co., Limited, arranged in the order of their efficiency when used in a Lancashire boiler fitted with Perret's furnace.

I have been enabled, through the kindness of Messrs. Bryan Donkin, and Co., to avail myself of these figures, which show at a glance the (comparative) value of Welsh coal as compared with other steam coals, of large Welsh as compared with small Welsh, of small anthracite, large and small coke, and coke dust; and, for the information of those who hope for great things from the use of town refuse for steam-raising purposes, I give at the foot of this table Messrs. Bryan Donkin's determination of its value. The Perret furnaces used for these determinations is well suited for making such a comparison, as it burns efficiently all classes of fuel, even the smaller and finely divided coals, coal dust, coke breeze, and coke dust, and in these cases minimises the loss of small combustible, which is liable to fall through the grate bars. The results shown on this table emphasise the fact that in practice we can utilise a large percentage of the T.U. in such fuels as anthracite, Welsh coal, and coke, the heating power of which lies chiefly in the solid carbon which they contain; and that the small and dust fuels of the same class are only less valuable because a part of them is liable to fall through the bars, and because, being so finely divided, they usually contain more earthy matter to form clinker and ash in the furnace than the larger coals or cokes, which can be more easily hand-picked, sorted, or washed free from such impurities.

The very large class of steam coals used in the Midlands and North is only represented in the table by the one test of the Yorkshire Ravensworth coal, but the majority of these coals, whether large engine coal, nuts, or engine slack, only contain from 50 to 70 per cent. of carbon in the solid form, so that although on account of the T.U. contained in the combined carbon and in the hydrogen, these fuels, when tested in the calorimeter, may give a calorific efficiency approaching that of the anthracite and Welsh coals, yet we find very rarely that any form of furnace now in use is able to utilise any considerable percentage of these hydrogen units, even when the best of the modern automatic stoking apparatus is used. So that when judging the comparative value of these fuels we should always remember that it is far more difficult to obtain a high boiler efficiency from these latter fuels than from those which contain the larger percentage of carbon in the form of coke. In order that you may conveniently calculate the T.U. contained in a pennyworth of coal of various qualities and prices, I have prepared Table V. (*a*), which shows this at a glance for all fuels from 10,000 up to 16,000 B.T.U. per pound, and for all prices from 5s. up to 22s. per ton.

FUEL AND WATER.—DIVS. 1 AND 2.—BOILERS, ECONOMISERS, ETC.

The boilers which have hitherto been chiefly used in electric supply works have been of the locomotive, marine or semi-marine, tubulous, or Babcock and Wilcox type, and the Lancashire type.

Locomotive Type.—Several large locomotive boilers were put in by Mr. W. H. Maw for driving the *Daily Telegraph* printing works, and the success of these was so great that I asked him to design for me boilers of the same type for the first London central station, which my firm put down for the London, Chatham, and Dover Railway at Victoria Station in 1883. These boilers had copper fire-boxes, and on test trials gave an evaporative efficiency of 8½lb. to 9lb. of water per pound of Welsh coal. This type is in most respects satisfactory, but on account of the level of the grate bars being so much below the level of the fire-doors, it is difficult to properly clinker the fires—so much so that when a batch of coal is used that contains much clinker it is very difficult to clean the fires in a reasonable time, so that the evaporative efficiency is thereby much reduced. From this cause the average efficiency of locomotive boilers does not much exceed 7lb. of water per pound of coal when taken from the monthly bills, and under the conditions usually met with in supply works. It is also not an easy matter to bank the fires of a locomotive boiler in an economical manner. The St. James's and Pall Mall Company have used large boilers of this type made by Davey, Paxman, and Co.; and the Metropolitan Company have used others made by Hornsbys—all, I believe, with good results. I, however, have been unable to obtain the correct evaporative duty. This type of boiler is rather more costly to maintain than the other types; the fire-door ring is liable to give trouble from leakage, and a great deal of space must be wasted in order to give access to the smoke-box end of the boilers for tube-sweeping purposes.

The Marine and Semi-Marine Type.—The marine type has been used in a few instances, notably in the Whitehall Court station of the Metropolitan Company, and is highly economical, but it is a rather costly boiler to construct. Equally good results may be obtained from the semi-marine type, which is a modification of it, made by Messrs. Davey-Paxman, and others, which they call the "Economic" boiler. In this boiler the flues are carried right through from front to back, and the products of combustion are deflected back through the tubes by a firebrick back. In Scotland this boiler is called a "dry-back" boiler. It has many merits. It is very simple, and easily repaired. The intensely-heated "dry-back" acts as a very good smoke preventer, so that Midland steam coals can be used without producing smoke, which is not the case with either the locomotive or Babcock's type. Prof. Kennedy has used a large number of these boilers for the Westminster Supply Company, and, he tells me, with uniformly good results from every point of view. The test of this boiler given in Table IV. shows it to be of the highest efficiency. I have not personally had much experience in its use until quite recently at the new central station in Shoreditch for the Great Eastern Railway. The sole fault in this boiler (and it is not a great one) is the rather awkward position of the smoke-box over the fire-door.

Babcock and Wilcox Boilers.—These boilers, as you well know, consist of a large group of inclined tubes, having the water inside the tubes, the highest end of the tubes being at the firing end of the boiler. The tubes are connected at both ends by special headers to steam-drums placed overhead. The firing is carried on on large grates, and the products of combustion are deflected by fire-tile bridges, so that they are obliged to follow a serpentine course through the tubes, the hot gases passing several times transversely to the tubes. My experience in the use of Babcock boilers has been altogether satisfactory, and I believe that the best evaporative efficiency yet obtained in supply works has been with these boilers. I make this statement all the more readily as in my 1891 paper* I said that this class of boiler, presenting as it does such considerable radiating surface of brickwork, would not give such economical results during the long hours of standing with banked fires as other boilers which are internally fired; but since that date the skill of the designers, and the great skill and attention of the users, has resulted in so minimising these losses, that I believe these boilers stand quite at the head of the list, not only as regards economical working on full-load tests, but also in the small use of fuel when standing banked. These are my own observations, but I understand that the experience of others has been equally satisfactory, at least wherever Welsh, anthracite, coke, or other smokeless fuels are used. I am told that when used with smoke-producing fuel there is a tendency for the lower rows of tubes to cool down the products of combustion, that these tubes become coated with soot, and the evaporative result is unsatisfactory. I believe, however, that the makers have now introduced special means to get over this difficulty. The chief refinements that those who use these boilers have been able to introduce, and which have led to reduction in the waste of fuel during long hours of light firing and banking, are principally in the alteration of ashpit, flue doors, and dampers, so as to regulate the air admission with great nicety, or to completely shut it off. We also find that the maintenance of the fire-tile bridges between the tubes which cause the gases to follow the undulating path above described is a matter of extreme importance, and last, but not least, this boiler should be kept perfectly clean. Up to a few years ago we were content with periodical cleanings and scalings; but now, by the use of suitable boiler fluids and frequent blowing off at the surface as well as at the lower cocks, we find that we can keep the interior of these boilers as free from scale, and in all respects as clean, as when they left the makers' hands. Test results with these boilers have shown that 9¾lb. of water can be evaporated with Welsh coal at 170lb. boiler pressure: if the calorific value of this coal is taken at 15,000, this is equal to 76½ per cent. efficiency; and, as my table of costs will show you, in practice we have reached to within a narrow percentage of this figure, even when all banking coal and other sources of waste are taken into consideration.

Lancashire Boilers.—We are told from time to time that the evaporative efficiency of this boiler ought to be the highest, and its maintenance cost the lowest, of any boiler. I believe the

* *Proceedings*, Inst.C.E., vol. cvi., p. 2.

Digitized by Google

latter claim to be better founded than the former. The boiler is easy to clean, and the repairs should be few at low pressures and far between; but it must be remembered that we have no extended experience of the cost of maintenance of these boilers when used at the higher pressures of 140lb. to 170lb. per square inch, now so common in electric works—as, for instance, the maintenance of the usual fusible plug is not an easy matter, and it is therefore necessary to depend on some form of low-water alarm, which is always a troublesome piece of apparatus; again, although the accidental lowering of the water-level of a locomotive or a Babcock boiler, or an "Economic" boiler may have serious consequences, yet these are nothing to what occurs when the flues of a Lancashire boiler come down from this cause. As regards the evaporative efficiency of the Lancashire boiler, I think it has been somewhat overrated. Owing to the fact that the great majority of Lancashire boilers are in use in the Midland and Northern counties, where the fuel used is cheaper than that we use in London, and where little or nothing is said if smoke is produced, and where low cost of maintenance is of higher importance than high evaporative efficiency, mill engineers have been led to regard this as the one and only boiler; but that this type is not efficient when taken by itself, is amply proved by the fact that no first-class mill is ever fitted up without the addition of economisers—in fact, we may say that the Lancashire boiler without its economiser is only half a boiler. In most cases the gases would leave the Lancashire boiler at 700deg., leaving 300deg. to be taken out of the gases by the economiser; whereas in tests of the locomotive, marine, semi-marine, or Babcock boilers the gases leave the boiler itself at a temperature very slightly in excess of that of the steam, so that in this latter case an economiser would be a refinement, and not a necessity. I do not think this fact has been sufficiently brought home to us engineers when the merits of the Lancashire type of boiler have been so persistently put before us by outside engineers, so that many of us—myself included—have made the mistake of putting down Lancashire boilers for supply stations in country towns without economisers, thinking that if we made these boilers large for their work we should get the required economy, whereas with this type the only way to get high economy is to use a rather small boiler and a large economiser. At any rate, the electric works using Lancashire boilers have hitherto not shown at all well in comparison with other types. In towns where the fuel is obtained so near to the works that the cost of carriage is small compared with the actual cost of the fuel itself, it pays to put down boilers fitted with special stoking plant to deal with these inferior fuels. In most of these cases Lancashire boilers have been used, but, as I shall show hereafter, the results hitherto obtained from the use of such cheap fuel have not been very satisfactory; in fact, the very cheapness of the fuel itself has been a snare to the works engineers, causing them to neglect refinements in fuel economy to such an extent that in many cases the greater part of the saving which they ought to have shown from the low price of their fuel has been lost. In some cases the price of their fuel has been actually higher than in the best London works, where economical working has been studied.

It is now time to put before you in a tabular form the data which I have been able to prepare to show the working efficiency of the boiler plant used in 10 of the works which I propose to compare. In all cases the quantity and calorific value of the fuel used is given with sufficient accuracy; but I have not in all cases been able to ascertain the water used per unit with the same accuracy, although this would have been a very desirable check on my other figures. Table III. shows the actual boiler efficiency in these 10 works; I have designated them by letters, which enable you to identify them, in the following tables:

TABLE III.—Boiler Efficiency.

Works.	System.	Type of boiler.	Fuel. Class.	Fuel. Value in B.T.U.	Lbs. of fuel per unit sold. 1892	1893	Lbs. of water evaporated per lb. of fuel.	Efficiency of boiler.

I would draw attention to the remarkably high results obtained by Prof. Kennedy, shown on Table IV., in his Glasgow trials, and beg that this result, which was obtained with marine-type boilers using small gasworks coke, may be compared with that shown by Bryan Donkin, in Table V., with a Lancashire boiler using similar coke. Referring to Table III., Works J are using Lancashire boilers fitted with automatic stokers of the Vicars type. In this case, which is under my own control, every means has been studied to increase the evaporative efficiency of the boilers; but this is a typical case of the difficulties attending the use of small coal, even if it be of fairly high caloritic value. In this case a considerable part of the loss is due to the small coal falling through the bars. The coal supplied is of variable caking quality: sometimes it cakes together sufficiently to reduce this loss; in other cases it hardly cakes at all, and from 15 to 20 per cent. of the combustible is lost. The point I have above referred to of the extreme difficulty of utilising the heat units in the hydrogen is here met with. If the air admission is not managed with the utmost nicety, the losses due to over-dilution of the products of combustion by air becomes so great that the evaporation is largely diminished, and this without any apparent neglect on the part of the stoker.

Before leaving the subject of boilers, I ought to say a few words on the use of forced draught. A good many of us have

formed the opinion that one of the best methods of meeting the short period of heavy load is by the use of forced draught applied to a closed ashpit, as has been done by Meldrun and others. It is evident that existing boiler plant might, in case of emergency, or for short periods, be forced to evaporate 50 per cent. more steam than at present; and this would be particularly convenient to meet the times of maximum load, so that in this way the waste of fuel due to lighting up extra boilers for these short periods might be reduced or altogether avoided. We should also be able to burn small or finely divided, and hence cheaper, fuel during the times of light load in an efficient manner. Another method of reducing the cost due to the necessity of lighting up additional boilers for the period of maximum load would be by using liquid fuel, to be used only on emergency or during these periods of maximum load. As is well known, Mr. Holden, on the Great Eastern Railway, has been very successful in the use of astatki, or crude petroleum, with his works boilers, and on some of the locomotives of the Great Eastern Railway. The principal objection to his system appears to be the noise of the blower, and the same applies to nearly all the systems of forced draught where an injector blower is used; but there seems little doubt that this noise may be minimised by properly arranging the air inlet—that is to say, by drawing the air from a point outside the building, placed so that the noise at the entrance cannot be a nuisance to the neighbours. As it is evident that it is very easy and convenient to safely store such liquid fuel in deep underground tanks, and, as is evident, in face of the troubles we have lately gone through from the coal strike, that it is necessary to have such a considerable storage, this question of the employment of liquid fuel deserves careful attention by all interested in supply works.

There is another point to which I wish to call attention. A long and interesting series of articles has recently appeared on water-tube boilers in the *Engineer*, in the course of which the writer more than once states that it is impossible to force any of the existing types of water-tube boilers, as any such forcing invariably results in the production of wet steam, and consequent loss of economy. It is difficult to know how the writer could have formed such an erroneous impression. My own experience is that the works where the best results have been obtained are those where the Babcock and Wilcox boilers have been forced the hardest. At Works W, the boilers, which are nominally supposed to evaporate 11,000lb. of water per hour, have frequently been forced to 16,000, or about 50 per cent. in excess of the duty guaranteed by the makers, and at such times of heavy forcing there has never been any trace of priming or wet steam.

On the whole, I think that there is a fair prospect of improving and supplementing our boiler plant and our methods of working it so that we may obtain in the future an average boiler efficiency of 70 per cent.—equivalent to an evaporation of 10lb. of water at a pressure of 150lb. when using Welsh coal, and an equivalent smaller evaporation from inferior and lower-priced coal.

Fuel and Water.—Divs. 1 and 2.—The Effect of the Efficiency of Steam-engines on Dynamos or Alternators.

Now that so many supply works have been running for several years, and that the works accounts have been annually published in the full detail demanded by the Board of Trade requirements, so that the actual cost of fuel, water, stores, labour, and salaries, and actual output of energy delivered, are recorded, and are known to everyone who interests himself in these matters, it might be thought an easy matter to draw some useful conclusions from these published figures, so as to throw light on the comparative efficiency of the various systems and types of plant used in these supply works, but I regret to be obliged to confess that the drawing up of such comparative tables is not an easy matter. I have examined the published accounts of 23 important and representative electric supply works in order to compare for this part of the paper the cost of the fuel. From these I have prepared Table VI., which relates solely to fuel and water used. I must mention that in preparing this and the other tables I at first relied on the published accounts for the information as to fuel, stores, labour, and salaries, but as I found that several serious mistakes existed in the published analysis of such accounts, I in every case have taken the precaution of sending the figures to the engineer of each works, in order that he might satisfy himself of their correctness, and in most cases the engineers of these works have very kindly supplemented this figure by the other data required to bring this cost of fuel to a common basis for purposes of comparison.

The best method of comparing the comparative efficiency of the generating plant would be by comparing the weight of water evaporated per unit generated; but, as I have already pointed out when discussing the boiler question, this water measurement has been very rarely carried out, so that I am obliged to fall back upon the only certain measurement—that is, the weight of fuel used. I have written to all the engineers of the works named in these tables, and have in some cases received full information, in others partial information, and in a few cases have been refused all supplementary information. In the case where the information has been partially, or where it has been entirely withheld, I have been obliged myself to fill in the blanks by calculating them from the published costs and known calorific values of the fuel used. I have done this after having made careful enquiry in each case; and whenever there has been a doubt as to quantity, price, or calorific value, I have endeavoured in each case rather to favour that particular works. At any rate, any errors that may exist in these calculated figures cannot be large enough to affect the result which I now bring before you. In addition to the accounts of the 23 works examined, I have also examined the accounts of 10 foreign works; but I find their information is too incomplete and too difficult to bring to a basis of comparison with our English works, and I do not complicate my table by adding them in. Of the 23 English works examined, 10—viz., those at Bournemouth, Chelmsford, City of London, Eastbourne, House-to-House (London), Metropolitan, Newcastle and District, Newcastle-on-Tyne, Leeds, and Exeter—distribute the bulk of their output on the converted alternating system. Two works—viz., those at Chelsea and Oxford—distribute on the converted continuous system. Eleven works—viz., Birmingham, Bradford, Brighton, Charing Cross and Strand, Hove, Kensington, Knightsbridge, Liverpool, Preston, St. James's and Pall Mall, and Westminster—distribute on the direct system.

In Table VI. I have grouped these 23 works into these three systems of distribution, and have arranged them in each group in order, always heading the list by the works that uses the largest quantity of fuel. It is curious to remark that this system of

grouping also divides them very fairly into the two great divisions of (1) rope or belt driven plant, (2) direct-driven plant. In the first group I have averaged the fuel consumption in T.U. per watt-hour, omitting from the average the first-named works, as the conditions of working are somewhat abnormal; and, similarly, in the last group I have averaged the fuel consumption for the whole, with the sole exception of the first-named works—*i.e.*, Preston—the conditions in this case being also abnormal. These averages show that the consumption of fuel per unit sold in the first group is about 94 per cent. greater than in the direct group: but as this difference is made up very considerably by the difference in efficiency of distribution, I have calculated the actual fuel consumption at the terminals of the dynamo by the efficiency of distribution of the two systems, which I regret to say is in several cases an assumed figure, as in several cases it appears to be actually unknown to the works engineers themselves. The table shows that, whereas the efficiency of distribution of the converted alternating systems is apparently somewhat under 66 per cent., with the direct systems (excluding the two-wire systems) it is about 86 per cent. The fuel used per unit generated in the converted alternating systems appears to be 43 per cent. higher than that used by the direct systems. In making these calculations I have carefully avoided considering those where a mixed system of distribution is used. The table also shows that the fuel average of the works where the alternators or dynamos are rope-driven is about 46 per cent. higher than where the dynamos are direct-driven by high-speed engines; and I think that the information that the table gives on this point is of the utmost importance, as it shows in a marked degree the economical advantages of high-speed direct-driven steam dynamos over slow-speed engines driving dynamos or alternators by ropes or belts.

Eight years ago I stood almost alone when I recommended that the 1,200-h.p. load of the Vienna central station should be divided amongst eight steam dynamos coupled direct to high-speed engines, as at that time most engineers still believed that high economy in the use of steam could only be obtained by putting down long-stroke slow-speed engines, such as are commonly used in cotton mills, and driving from these engines the dynamos by means of ropes or belts. This superstition was founded on the belief that steam could only be economically used in large engines of this type, which obtained their high piston speed by long strokes and few revolutions per minute; but it did not take long to show that the great variations of load in an electric supply works causes these huge engines to run for many hours at a very small fraction of their load, making them very uneconomical, so that the subdivision of their load between several smaller engines became necessary.

Mr. Willans, in his first and historic paper on steam-engine economy read before the Institution of Civil Engineers, was the first to strike a blow at the erroneous belief that economy could only be obtained from long-stroke, slowly-revolving engines, by showing that as the enemy to economy, particularly in the smaller engines, is cylinder condensation, the true way to reduce this is not by mere piston speed, as was the current belief, but by reducing the time during which the cylinder surfaces are exposed to the cooling action of the exhaust or of the condenser previous to each fresh steam admission—in other words, by using rapidly-revolving short-stroke engines instead of slowly-revolving long-stroke ones. Once this was understood, it followed that the high-speed engine making many revolutions, and therefore best suited for coupling direct to our dynamos, is also theoretically the most economical in use of steam. That this is also true in practice is shown by the long series of experiments carried out by Mr. Willans and the figures that I am now putting before you. The advantages of direct driving are obviously not confined to the Willans, or, indeed, to any single-acting, type of engine; in fact, we have now a considerable choice of high-speed engines, all of which can be coupled direct to dynamos, and which use their steam economically. There is one advantage common to all direct-driven steam dynamos—*i.e.*, their high efficiency in $\frac{\text{E.H.P.}}{\text{I.H.P.}}$ This efficiency, which has been gradually creeping up from 80 per cent., which was the efficiency we obtained from the Vienna steam dynamos in 1886, to the very high figure of 88 per cent., which has recently been obtained by a Willans-Siemens combination, has been much commented upon, and has in some quarters met with actual disbelief; but all who know how accurately the tests have been carried out at Thames Ditton, and who have themselves made independent check tests, know also that such an efficiency can be obtained without difficulty—in fact, that efficiencies in excess of 86 per cent. can now be guaranteed at full loads, and 80 per cent. at half loads.

The case is far different with rope or belt driven sets. In most cases it is difficult to obtain an efficiency of 78 per cent. at full load and 70 per cent. at half load when the engines are fitted with the ordinary unbalanced slide valve, or 80 per cent. at full load and 73 per cent. at half load when the engines have Corliss or balance valves. I must, however, note that Mr. Parker, in his paper—read before the Institution of Civil Engineers—on the Liverpool Overhead Railway, gives us the satisfactory results obtained from slow-running horizontal engines driving dynamos by ropes; but, although I do not challenge Mr. Parker's ultimate figures, yet I think that without doubt he has made a mistake in his calculated efficiency—that is to say, $\frac{\text{E.H.P.}}{\text{I.H.P.}}$. I think that it would be difficult for me—or, in fact, for anyone who has paid much attention to the losses due to the friction of steam-engines, and particularly of condensing engines, and to the losses occasioned by rope-driving—to accept Mr. Parker's figures. No one has made more careful experiments on the friction of such engines than Messrs. Sulzer, of Winterthur, and Messrs. Carels Frères, of Ghent, who make the same type of engines. I have been informed by the latter that an engine efficiency of 91 per cent. is only rarely obtained; generally, the efficiency is somewhat lower. Mr. Parker states that the electrical efficiency of his dynamos is 97·7 per cent., which is an extremely high figure. If we take the commercial dynamo efficiency at 96 per cent., which is an outside figure when we consider the side strains on the bearings caused by the rope-driving, and if we suppose that the loss due to the rope-driving is only 2 per cent., which I believe is less than has ever been noticed, it is just possible, with a 91 per cent. engine, a 2 per cent. rope loss, and a 96 per cent. dynamo, to get 86·6 per cent. efficiency.

Although I do not believe that such an efficiency, and correspondingly small consumption of steam per electrical horse-power at full and half loads can be obtained in practice by engines driving dynamos by ropes, yet it is so often attained by direct-driven sets that at least one maker can now guarantee figures very closely approaching the ideal figures I have given of 18½lb. of steam per unit at full load, and 21½lb. at half load. Yet in the cases of direct driving such high efficiency is easily accounted for. In the first place, the engines are fitted with piston-valves, which are the most perfect form of balanced valves; hence the internal friction of the Willans or Chandler engines, running as they do with all their parts thoroughly bathed in oil, must be probably lower than that of any other type of engine. Moreover, with direct driving there is no side strain whatever on the dynamo bearings, and even the downward pressure on these bearings can be partially eased by so placing the armature core in relation to the bore of the magnets that a certain amount of lift is given to the core at the time that the magnets are excited. Under such conditions it will be seen that the engine and dynamo mechanical friction can be reduced to a minimum—in fact, to a point very far below what is possible when any form of rope or belt driving is used. The figures that I now give show that the best results yet obtained have been with Willans engines driving direct-current dynamos, and I believe this is mainly due to the great reduction of friction which I have just mentioned, and which tells heavily in favour of this class of steam dynamo when it is only partially loaded. Hence we find that, whereas the combined efficiency of a Willans combination is as high as 80 per cent. at outputs as low as two-thirds full load, the combined efficiency of two-thirds load of a slide-valve engine driving a

Digitized by Google

dynamo by belts or ropes rarely exceeds 70 per cent.; and, unfortunately, however much we may desire to keep the load-factor of the engine above 66 per cent., or two thirds, yet under existing circumstances it is a matter of difficulty to do so even in works where accumulators are used, and in works where there are no accumulators with all converted systems the average engine load-factor appears to be far below this.

As you no doubt expect me to express an opinion as to the cause of the wide differences in economies of fuel shown in these comparative tables, I must point out that, even if we exclude the difference in distribution efficiency by making the allowances that I have done, there still remain three sources of loss—one already dealt with under the heading of the boilers, and the second due to the engines, dynamos, or alternators, and the third to losses which have been called by Kennedy "obscure works losses." Now, I think the main cause of the difference in engine and dynamo losses lies in the fact that in the works under consideration the engines have been driven at widely differing load-factors; and, as whenever the engine load-factor is low the use of steam is correspondingly high, I think that this question of engine load-factor is of supreme importance. As I have shown above, a low engine load-factor tells more against belt or rope driving sets than against direct-driving ones; but in neither case has the subject received the attention that it deserves. Every facility should be given for the men in charge of the steam dynamos to ascertain for themselves at any time at what load-factor they are driving their plant, and if this were done more frequently I am sure that great improvements would result. One reason why at present the men in the supply stations know so little about this question is, that in most cases it is only looked into as a sort of holy mystery by the engineering staff, and at long intervals of time; whereas I feel strongly a book ought to be kept in every works, and the men in charge should always enter up the load-factor of each engine during the hours the stop valve is open; and in order that this may be done with a minimum of labour, I have devised and used in our Chelmsford works a system which I will here describe for the benefit of those who care to adopt it. The diagram before you has its base line marked off in percentages of the load of the engine; and the same line is, in addition, marked with the steam-chest pressure, corresponding to these different percentages of load. This steam-chest pressure can be noted by a carefully calibrated gauge fixed on the steam-chest of the engine, the calibration being carried out as each set of indicator diagrams and electric load readings are taken; the result being that the man in charge of the engine can see at a glance from these steam-gauges what ought to be the indicated and corresponding electrical horse-power that his engine is giving, and from the same diagram he is able to calculate the consumption of pounds of steam per hour. Opposite to each gauge pressure is entered the theoretical consumption of steam per horse-power per hour at the standard speed, ascertained from Mr. Willans's table. Thus, if the man in charge enters up these steam pressures of all the running engines every quarter of an hour, it is easy to prepare an accurate report on the engine load-factor of the day, and thus compare the calculated with the actual steam used during the run, so that men who habitually underwork their engines can be thus noted and reprimanded. Of course, I know from experience how much more difficult it is to work engines driving alternators at a high load-factor than is the case with continuous-current steam dynamos. This is partly caused by the comparative difficulty and complication involved in parallelising alternators, compared with the ease of throwing continous dynamos in and out of parallel on a storage system. In the latter case, the enginemen have only one order to observe—viz., to keep their engines as fully loaded as possible on a rising load, not to start an additional set until the sets previously running are considerably overloaded and on a falling load to shut down the sets at the earliest possible moment, even if it leaves the remaining sets somewhat overloaded for some time. Unless such orders are given and carried out to the letter, so that engine load-factors exceeding 70 per cent. on the average are obtained, it is useless to expect to reduce the consumption of steam below 50lb. per unit generated.

The other causes of waste of steam in electric supply works are those which Prof. Kennedy, in his lecture at the Royal Institution, speaks of as "losses about which we engineers feel very sore, and which sometimes try our temper and our patience greatly, and are not recognised as having any kind of respectable existence." These are those connected with leaks from boiler fittings and steam-pipes, with condensation losses in the steam-pipes, and due to the wasteful use of steam by all present known means of boiler feed. These losses have been ignored by engineers, and have never received the attention they deserve; but as they continue throughout the 24 hours, they amount to a very considerable percentage of the steam evaporated by the boilers, and, of course, tell most during the summer months, or, in fact, in any works where the load-factor is low. Engineers who have been most successful in dealing with these difficulties, and have minimised these losses to the greatest extent, are those who previous to entering electrical works have received a practical engine-room training, either as sea-going engineers or in engine-rooms of a similar class where fuel economy has been persistently studied. I believe the best remedy for the pipe condensation losses will lie in the direction of superheating the steam after it leaves the boilers. If we could superheat the steam so as not only to have no pipe condensation at all, but to deliver the steam to the engine cylinders at a temperature 8 or 10 per cent. above the corresponding temperature for saturated steam, I believe that we should at once save nearly 10 per cent. of the steam that we now have to evaporate in our boilers. It is very easy to talk of superheating steam. In the days of low-pressure steam at 15lb. pressure, such superheating was a reasonably easy matter; but the case is widely different when the high-pressure steam leaves the boiler at a temperature of 375deg., as is now the case. Any further superheating is very much in the nature of passing this steam through pipes at a temperature which nearly amounts to red heat, so that it is little wonder that not many engineers have cared about tackling such a difficult and risky problem; but it is quite certain that this problem will be tackled, and I have recently heard that it has been satisfactorily dealt with by Messrs. McPhail and Simpson, the superheater consisting of a large number of bent tubes made of thick lap-welded iron, each tube being only about 1in diameter. The bent portions of these tubes are so placed that they are exposed to the hot gases when they first pass through the flues of the boiler, such as the space at the end of a Lancashire or of an "Economic" boiler; in the case of the Babcock boiler it would be more difficult to find a place for them. It is evident that whoever attempts to deal with this problem of working out a satisfactory superheater will have a great many difficulties to deal with. The superheater must, as I have said, be placed so as to be exposed to the high temperature gases, and yet it must be accessible for ready replacing of the tubes and for repairs. Moreover, it must be easily put in and out of circuit, so that a failure of one of the tubes should not in any way cripple the steam supply of the works. These requirements are in a sense contradictory, but I have no doubt, now that so many minds are directed to this problem, it will be successfully dealt with.

Another point which is receiving the attention of all of us is the extended application of condensing plant. In situations where condensing water is available this problem presents no difficulty, but in a large number of cases condensing water is not available; and of late years—in fact, dating from the time of my 1891 paper—a number of proposals have been made to introduce what are called evaporative or surface condensers, which may be described as consisting of a very extended surface of tubes, through which the steam passes, the tubes being cooled externally, partly by an air-fan blast and partly by a limited supply of water trickling on to the outside of them. Of course, so long as the amount of water used is equal to the feed water used, there would be no advantage in using such a condenser, other than that the steam consumption may possibly be economised, especially at times of light load, so that the steam that is required to pass through the condenser would be proportionately reduced; but Mr. Ledward and several other gentlemen who have paid attention to this subject are confident that they will be able to eventually reduce the cooling water required to two-thirds of that of the ordinary feed water; and if this is the case, it will result in a very great advantage, not only in removing the nuisance—which some people insist is a real nuisance—of the steam issuing from the chimneys of the various supply works, but the difficulties with the boilers will be also greatly diminished. But it must be recollected that this use of condensing water entails the working out of several very difficult problems connected with the thorough filtering out of the oil contained in the exhaust steam before it is allowed to re-enter the boilers. The united opinion of nearly all boiler engineers and inspectors is to the effect that if the water contains the smallest percentage of carbonate of lime the entry of even minute quantities of oil into the boiler is likely to have disastrous effects. The oil forms with the carbonate of lime a covering to the flues and tubes of a highly non-conducting nature, which allows the iron or steel plates or tubes to be greatly overheated, and great damage is thus done; so that most boiler insurance companies absolutely forbid the returning of condensed water to the boiler unless it has previously passed through a purifying apparatus which absolutely frees it from the oil.

I have briefly mentioned how very considerably the wasteful nature of the steam-pumps that are at present available for boiler-feed pumps affects the total economy of the works. For some time past at Chelmsford I have attempted to deal with this difficulty by supplying my boilers with feed pumps electrically driven; and although these electrically-driven feed pumps are by no means as efficient as I hope to make them in the future, yet in their present state their use shows a marked economy over the Worthington or other direct-acting pumps that were previously employed. The electrically-driven pumps use the energy from the main switchboard, which is generated in an economical manner; whereas the direct-driven pumps are driven not so much by steam as by water condensed in their steam-pipes. I have over and over again called the attention of pumpmakers to the great want there is of a more economical steam-pump than is at present in the market; but there appears to be a difficulty in dealing with the question, I believe chiefly owing to the intermittent way in which these feed pumps are worked, so that between periods of working their supply steam-pipes get comparatively cooled. I have spoken of the difficulty I have met with in obtaining trustworthy figures as regards water consumption. This is mainly due to the fact that a thoroughly trustworthy water-meter is not an easy article to meet with. In order that such a water-meter may accurately record the water fed into the boiler, it ought to be placed between the feed-water heater and the boiler, so that any leakages that may occur at the pumps themselves, or in the line of pipes, or in the feed-water heater itself, may not affect the question of boiler evaporation. This necessarily means that such a water-meter must pass hot water. For several years past I have been using Schönheyder's meter in this position, with fairly satisfactory results, but in its present state it leaves much to be desired. The pins wear to such an extent that in our Chelmsford case we find it necessary to take the meter out and replace the pins and recalibrate it once every three or four months. The calibration of such a meter is not a difficult

Digitized by Google

matter if the feed water in any part of its course passes through a rectangular tank, the cubic contents of which can be readily measured, and the water contained marked for each inch of height.

When speaking of the differences which exist between the calculated consumption of fuel and water by the plant when tested under full load, and that which is observed from the water and coal bills in the month's or year's working, I was at one time doubtful whether any single 24-hour test would include within it the observed losses; but during the past year, having made a large number of such 24-hour tests at our Chelmsford works, I have come to the conclusion that such 24-hour tests which follow a complete cycle of the working are a fairly trustworthy guide to the annual losses; and I cannot too highly recommend the practice of taking such tests, and of showing them graphically in the manner universally adopted by mechanical engineers, and shown by Prof. Kennedy in the discussion which followed on my paper in 1891. Diagram VII. shows the way in which we plot a 24-hour test at Chelmsford, and this may be applied to any other works. Many of you will ask how I have been able to obtain the electrical work at the terminals of the dynamo in the case of the Chelmsford works, where we use alternating dynamos. My answer is, that it is only during the last few months that I have been able to do this; and it is owing to the extreme kindness of Prof. Fleming, and his unwearied attention in perfecting the Mengarini wattmeter for our purpose, that we have been able to obtain a daily record of the electrical energy generated by our alternating plant, as well as that generated by our direct plant. Diagram VIII. shows an enlarged diagram obtained from this wattmeter, and we have divided it up into known portions of the load from cards taken on other nights. We are able to separate the load in the town shops from the load in private houses owing to the fact that it is the custom at Chelmsford on Wednesday night to close all the shops, so that our load on that night consists entirely of the public lighting, which is an ascertained and invariable quantity, on which is superposed the lighting in the private houses only. It will be interesting to many here to know that the circumstances under which we work at Chelmsford of supplying the light between certain hours has enabled us to greatly cut down the transformer loss, so that we have been able to show an efficiency of distribution reaching 76 per cent., which I believe is probably as high as has ever been reached with alternating plant; but if we were compelled to keep the supply up through the remainder of the 24 hours, I am afraid the state of affairs would be widely different. We are also aided by such a large part of our load being public lighting, which goes on throughout the entire hours of darkness in summer and in winter.

Fuel and Water.—Part III.

Effects of Distribution Efficiency.—I am obliged to introduce this question into this paper, as there can be no doubt that the high consumption of fuel shown by certain works is partly due to low distribution efficiency; but I do not propose to dwell on this highly important question, which merits a paper to itself, besides being of a highly controversial character. I find that in few cases have the engineers of supply works had the pluck to face this important problem, and to ascertain and state boldly what distribution efficiency they have noted. In several cases, however, this has been done, so that I am able to make the Table VI. reasonably complete. From it you will see that the efficiency of distribution of direct systems, including meter losses, varies between 85 and 91½ per cent., whereas that of converted systems varies between 60 and 82 per cent.; the higher figure being only found where the system of switching transformers in and out of circuit is practised. In the very small loss of from 10 to 12 per cent. observed in the direct systems are included all those due to the accumulators, to the C^2R losses in the mains, to leakage, and to meters failing to register; and I do not think it is likely in the future we shall be able to improve much, if at all, on this distribution efficiency—in fact, we are assured by our American friends that it would pay us better to somewhat reduce this efficiency by putting less copper in our mains; but we consider that our English practice is right, as in order to get thoroughly steady lighting and good regulation it is necessary to work at this high efficiency, and at the present price of copper it can be easily shown that it pays to do so.

Stores, Water, Labour, and Superintendence.

Under the head of "Stores used in the Generating Works" are usually included water (which in London and many other towns has to be paid for), oil, grease, waste, packing, gauge glasses, and other materials which are from day to day used in the working of a supply works. The decrease in the stores item in several of the companies has been very noticeable during the last few years of working. In the case of the Kensington Court works of the Kensington Company, the stores have in some months reached as low a figure as 0·025d. per unit sold, and there is no doubt that even a lower figure will be reached as the output and load-factor improve. In this question of use of stores the closed type of engine, such as those made by Messrs. Willans, Bumsted and Chandler, and Bellis, of Birmingham, compare most favourably with the open type of engines. During a visit paid to Vienna two years ago, I was told by Mr. Melhuish, the engineer-in-charge of the Imperial Continental Gas Association, that the consumption of oil by an open-type compound engine which they had recently erected in that station was 16 times as great as the consumption of oil by a Willans engine of equal power, and I think that in many cases differences almost as great as this will be observed between the two types of engines. When it is considered that in the close type the only glands there are to pack are those of the governor gland and at the two ends of the crankshaft, whereas in a compound or triple open-type engine there are certainly not less than eight important glands to pack, and not less than 20 oiling points requiring separate attention, it will be seen how great the difference is. In the case of rope-driving sets there are in most cases three dynamo bearings to be oiled instead of the one bearing in the case of the direct-driven set, and the side strain on the bearings necessitates nearly a fivefold use of oil. Table VII. gives the cost of stores in the same works as Table III., from which it will be seen that whereas some of the works using direct-driven plant have already come within a measurable distance of the figure of 0·03 for water and petty stores, those using belt, or rope driven sets, are a very long way from it.

Table VII.—Comparison of Stores, Wages, and Superintendence Costs.

Ideal works	N to Q, S to W	0·03	0·2	

Items 4 and 5.—Wages and Superintendence in Works.—On Table VII. I also give these two items for all of the works, showing a somewhat slow progress towards my ideal figure of 0·2d. per unit. This table shows that the lowest figure yet reached is 0·38d. per unit; but, as this figure is very largely a question of output, it is certain that from the increase of output alone, and without the introduction of any refinements having for their object the reduction of the staff employed in the stations, the wages and superintendence charge may be easily brought down. It is evident, however, that this charge must be much higher in the case of belt or rope driven machinery than is the case with direct driving, and Table VII. shows this to a very marked extent. There is every reason to believe that with direct-driving closed-type engines 1,000 kilowatts will demand the services of only one attendant, whereas it is doubtful whether with rope or belt driven and open engines one man could attend properly to more than 600 kilowatts of plant. This, however, is only my opinion, as in neither case has the output of any existing works been sufficiently large to enable the attendants to have their time occupied in the most profitable manner; it is quite certain, however, that under present conditions the use of accumulator storage has a most important effect on reducing the cost of attendance. Whether this will be so in the future, when the all-night loads begin to be heavy, I am at present not able to say, but I hold a very strong opinion that a proper proportion of accumulator storage will even in large stations reduce the cost of attendance at least 30 per cent., and in smaller stations from 40 to 50 per cent.

Maintenance.—I have considered this part of the subject with considerable care. It is the one point on which existing opinions vary through very wide limits, and, as far as I can judge, opinions incline at present in what I believe to be an unsafe direction—that is to say, too much has been made of the extremely light cost of repairs of existing works during the few years that they have been

Digitized by Google

running, and figures have been founded on this which I am afraid will turn out to be altogether illusory. In all other businesses the upkeep of boilers which require to be periodically fired up and cooled down, and which have to be heavily fired at times of maximum load, is put down at a figure varying from 5 to 10 per cent. on the original cost of the boilers. The upkeep of steam-engines when worked at a far easier rate than is usual in electric supply works is usually taken at from 3 to 5 per cent. on their first cost; whereas the published accounts show that nothing like these figures have hitherto been spent on, or put aside for, the maintenance of these parts of the plant. I do not think that any accurate estimates can be formed of the ultimate cost of maintaining electric generating and distributing plant, other than on a percentage basis such as I have introduced in both my previous papers. I have therefore prepared Table VIII. to show what has been my own experience in this matter. This table gives the actual sum spent on the maintenance of various parts of the plant of the works of the Kensington and Knightsbridge Company during the last four years out of the seven years that this company has been supplying electrical energy. I have given in the table the original cost of each part of the plant, and have worked out the annual percentage cost which the maintenance bears to the original cost. As some of the steam-engines and boilers of this company have been at work seven years, and the bulk of the plant has been at work five years, sufficient time has elapsed for the maintenance cost to have settled down to the figure at which it is likely permanently to remain. As might be expected, the upkeep of the boilers and the accumulators has been more costly than that of any other portion of the plant, but in neither case is the amount as high as I expected it would be. The noticeable feature is the very small sum spent on the upkeep of the engines, of the dynamos, and of the mains.

TABLE VIII.—Cost of Maintenance of Works for a Period of Four Years—1890, 1891, 1892, 1893.

Description of plant.	Original cost.	Spent on maintenance in four years.	Per cent. per annum on cost.
	£	£	%
Buildings	16,598	429	0·65
Boilers	8,124	1,704	5·23
Engines	9,900	704	1·77
Dynamos	8,660	264	0·76
Other plant	12,868	968	1·9
Accumulators	15,115	1,968	3·25
Mains and services	65,167	952	0·36
Meters	6,549	628	2·5
Total	£142,981	£7,616	1·35%

The cost of upkeep of the engines is confined to the substitution of small parts as they wear, by new parts supplied from store. It will be seen that the upkeep of the dynamos is almost nil; but I must direct particular attention to the small sum spent on the inspection and maintenance of the mains, as this vindicates my often-repeated assertions that a well designed and conducted bare copper system must cost less to inspect and maintain than any system of continuously-insulated cables. At any rate, the sum expended on mains as shown in this table is an outside sum, as it includes many alteration items which can hardly be considered as fair wear and tear, but rather in the nature of improvements, and thus chargeable to capital. The maintenance sum spent by this company has been sufficient to keep the plant in absolutely as good order as when it was first put down, and, as I have just said, in some cases has enabled improvements to be introduced which have been charged to revenue. This gives me hopes that future experience will not show any marked increase in these percentage rates, but rather the reverse; so that the ideal figure I have proposed of 0·4d. per unit, which on 5,000,000 units will yield the very respectable sum of £8,300 per annum, will be a sufficient sum to maintain the entire plant in perfect working order for ever.

I have now taken you through all the items of cost of an electrical supply works, and have endeavoured, as far as possible, to compare what has been done up to date with an ideal possible standard. Whether this standard be ever reached or no, I think it will serve the useful purpose of holding before you a goal which we may all strive to attain, and that without the necessity for bringing out any wonderful revolutions in our practice, or, in fact, doing anything but intelligently perfect and use our present appliances. I hope my efforts in preparing this paper will be appreciated by those to whom it is addressed. I personally have the warmest sympathy with and admiration for the work of the large number of young electrical engineers who are now scattered over the various supply works, and to whose efforts we are indebted for the very marked advance in economy that I have this evening brought before you. I sincerely hope and trust that the means I have adopted of circulating the paper before the meeting will have given time to these works engineers to appreciate some of my points, so that we may have the advantage of having the important questions that I have raised, ventilated and discussed by those who are most competent to do it—namely, the resident engineers of electrical supply works.

I cannot conclude this paper without expressing my thanks to the very large number of gentlemen who have assisted me in my labours. In order to get together the data necessary for the production of this paper, I have had to visit a number of stations, and write a large number of letters to the engineers of stations which I could not visit. As it may be the wish of many of these gentlemen to preserve their anonymity, I do not thank them by name. As regards stations with which I personally am closely connected, the importance of anonymity is not so great, and I have therefore the pleasure in stating that much of the splendid results that have been obtained from some of my own stations—the figures of which no doubt some of you have recognised in the tables before you this evening—are due to the continued hard and intelligent work of Mr. Miller, the resident engineer at Kensington; Mr. Barley, the resident engineer at Knightsbridge; and Mr. Pott, the resident engineer at Chelmsford.

[We are unable to give with this report the illustrations accompanying the paper. The text is fairly understandable without them, but we hope to be able to give the illustrations with the report of the discussion.—ED. *E. E.*]

At last night's meeting of the Institution the following candidates were balloted for:

Associates.—John Henry Bale, Lynton and Lynmouth Electric Light Company, Lynmouth, North Devon; Arthur Bentley, Electric Construction Company, Limited, Ferdinand-street, Chalk Farm; William Clay, 13, Claude-road, Roath, Cardiff; Christopher Charles Hart, jun., 404, Uxbridge-road, W.; Peter Charles Middleton, 115, Union-street, Aberdeen; Benjamin Young, 8, Coleshill-street, Birmingham.

Students.—Archie S. Cubitt, 85, Tyrwhitt-road, St. Johns, S.E.; Albert Alexander Horn, Hazledene, New Barnet, Herts.; Owen David Lucas, 10, Westbourne-terrace, Hyde Park, W.; Percival Thomas Moor, 17, West Hillary-street, Leeds.

LIGHTING POWER OF ALTERNATING ARC LAMPS.

In a work recently published concerning the Cologne and Amsterdam electricity works, some interesting information is given of the lighting power of alternating-current arc lamps in the latter town. They are 10-ampere lamps, and the results are as follow:

Volts.	Amperes.	Watts.	Intensity of light in normal candles. Horizontal.	Maximum.	Spherical.
28·5	11	313	150	550	275
32·5	10·5	341	93	423	205

It will be seen from these figures that a greater pressure than 28 volts is not advantageous. Further experiments with these lamps were made in the direction of ascertaining the influence of the current strength upon the lighting power of the lamps. The results were as follow:

Current in Amperes.	Pressure in volts.	Intensity in normal candles. Horizontal.	Maximum.	Spherical.
50	25	1,630	4,840	2,625
30	28	1,800	3,880	2,200
20	27·5	940	3,760	1,500
16	28	925	2,160	1,200
15	27·5	670	1,570	870
10	28	150	550	275
8	30	92	530	250

CORRESPONDENCE.

"One man's word is no man's word,
Justice needs that both be heard."

THE NORTHERN SOCIETY OF ELECTRICAL ENGINEERS—A CORRECTION.

SIR,—In the report of my remarks during the discussion at the above society, published in to-day's issue of your paper, you give me credit for more than I deserve. The last 30 lines of my remarks (as given) should be put down to Mr. Nisbett's account, as he is responsible for them.—Yours, etc., JOHN H. RIDER.

Bolton, April 20, 1894.

SIR,—In my paper read before the Northern Society of Electrical Engineers on April 9, I am reported to have said that a meter on the principle of Ferranti's mercury bath was designed and exhibited by Lord Kelvin. As a matter of fact this is not the case, and I corrected myself while reading the paper. A meter on this principle was first designed in 1883 by Mr. Ferranti, and another of his patents covers the principle of partially floating the fan immersed in the mercury bath.

Thanking you for inserting this correction—Yours, etc.,

London, S.W., April 23, 1894. R. P. WILSON.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.*

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140 Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** *for a series can be arranged on application.*

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" *can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—*

	3 months	6 months	12 month
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d
Other Places	4s. 11d	9s. 9d.	19s. 6d

(Post Free Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscription and Advertisements should be made payable to C. H. W. BIGGS, *139-140, Salisbury Court, Fleet Street. London, and be crossed "Union Bank."*

BOUND VOLUMES.

Vol. XII. of new series of "THE ELECTRICAL ENGINEER" can be had bound in blue cloth, gilt lettered, price 8s. 6d. Subscribers can have their own copies bound for 2s. 6d., or covers for binding can be obtained, price 2s.

WHEN DOCTORS DIFFER, WHO SHALL DECIDE?

In our opinion, as we have often pointed out, one of the greatest developments of electricity in the future will be in sanitary work. Holding this opinion, we awaited with considerable interest the result of the Worthing experiments, and gave the report of Dr. Kelly in full. Since then we have received the report of Dr. Alain Piton made to the Municipal Council of Brest. These two experts differ considerably in their conclusions, although made upon the same process. In asking how such differences can arise, we are led to the conclusion that in one case inferences must have been deduced from too few data. As yet but two systematic attempts have been made to employ electricity in sanitary work on a large scale—those of Mr. Webster and M. Hermite. Of late, Mr. Webster's process seems to have dropped somewhat out of competition, while M. Hermite's has come on. The main argument for the necessity of using some artificial method of disinfection is that, under existing conditions of civilised life, Nature has neither the time nor the opportunity of doing this work. According to the teaching of the time, Nature's great disinfectant is oxygen, and given enough oxygen in an active state, danger of infection may be averted. Now both Webster's and Hermite's processes provide for enormous quantities of oxygen either directly or indirectly, and profess to do in a short time and under given conditions the work for which Nature requires more time and different conditions. Electricians know little about sanitary engineering; they know little of sewage schemes, sewage farms, or effluents, but of these they must learn. The land suitable for sewage farms cannot always be obtained near large towns, the sea is not always available, and other means than pouring the sewage into rivers must be adopted. As population increases, the question of sewage treatment becomes more and more important. An electric current enables us to generate at will the required disinfectants, whether oxygen or chlorine. M. Hermite's system, as we have said, has been reported upon in two different quarters, with two different results. The concluding paragraph of Dr. Kelly's report (*Electrical Engineer*, April 6, page 413) reads as follows: "Since there is no instantaneous decomposition of fæcal matter, and *no sterilisation of sewage, etc.*" The italics are ours. Turning now to Dr. A. Piton, page 18, we read, "Ten cubic centimetres of electrolysed solution at 1 per 1,000 sterilises in half an hour one cubic centimetre of simple culture in broth of cholera bacillus, typhoid bacillus, or bacillus subtilis 'spore.'" Other experiments with different strengths of solution gave similar results, and he goes on to say, "One may then conclude that the antiseptic action of electrolysed sea-water is evident on the bacilli after half an hour of contact. Further trials will determine if the dose of antiseptic and the duration of contact may be reduced." Dr. Piton is not content with examining the action upon culture, but pointing out that unless the action is similar upon fæcal matter the antiseptic is useless. He carried out a number of experiments upon fæcal matter, and says, page 26, "It requires more than 80 cubic centimetres of

Digitized by Google

electrolysed solution of 0·25 gramme strength to sterilise one gramme fæcal matter." He also gives the results with other strengths of solution, considering both time and quantity necessary for sterilisation. It is unnecessary to quote more as to sterilisation: enough has been said to show how diametrically these two reports are opposed. We will only quote one more sentence from Dr. Piton. He says, page 28, "Urinals, house refuse, and bilge water in ships are quickly and effectively disinfected." This is a definite statement, and again is opposed to that of Dr. Kelly. So far as we can judge, the conclusions arrived at by Dr. Piton are from a far longer and more systematic series of experiments than those of Dr. Kelly, and it may be that less care was taken in the latter case to test the strength of solution, or to find the time required by the solution for complete action. Too great stress, indeed, seems to have been laid upon instantaneous action—an action that will never be obtained in practice, and one that is not at all necessary. A certain time can always be given for the action of the disinfectant or antiseptic, but it is important to know both time and quantity in order to satisfactorily design the required works. We hope these divergent expressions of opinion will be thrashed out in the paper which we see is promised from M. Hermite to the Society of Arts. It will be a pity if the inventor of the system which has been reported on lets the session pass without bringing the matter forward; hence we trust to see a definite date given for this promised paper.

PROF. KENNEDY AT THE MECHANICAL ENGINEERS.

From a communication elsewhere in our columns it will be seen that Prof. Kennedy's remarks upon electrical traction are not to go without adverse comment. While, however, there are in this excellent address remarks with which we differ, we are not quite sure that Mr. Lea fully grasps the tenor of those on traction. There is, of course, the usual divergence about actual figures, but, on the whole, the difference of opinion may be summed up in a few words. It seems to us that the text, or at any rate one text, of the president of the Mechanical Engineers is that, other things being the same, the interposition of another piece of apparatus in a chain of mechanism decreases the efficiency of the combination, and this no matter how efficient the apparatus may be in itself. Mr. Lea will no doubt agree to this, but he contends that though there may be a decreased efficiency in one direction, you are able to get a new combination and increase the efficiency in another direction. He contends, in fact, that the stationary engine is the more efficient, and this increase of efficiency more than counterbalances the decrease of efficiency between the points of generation and use. We are quite content to let time operate in bringing these divers opinions nearer together. Prof. Kennedy would no doubt argue that he perfectly understands the expediency of utilising electricity in certain cases, and that its use would show to great advantage over competitors, but that generally his conclusions are legitimately deduced. We do not think the question of electric traction is to be decided generally by any comparison with steam; hence our greater or less indifference to controversy on this particular part of the subject. Steam traction on tramways will not be tolerated in thickly-populated towns to any great extent. It exists in a few cases, but in each of these it is tolerably clear to the initiated why it so exists. The great question is, horses or electricity; and in the long run horses must go, even if it be only to please the goody-goody folks who love horses and hate cruelty, for in this case civilised cruelty is worse than that of savagedom. However, the ruling point is cost of horses *v.* cost of electricity, and if the latter can be shown by its supporters to approach the former, depend upon it, electric traction will gain in favour and be installed as quickly as financial considerations permit. Steam traction (at any rate as at present known) *v.* electric traction for general work on tramways is not within the bounds of practical politics.

A SYSTEM OF NOMENCLATURE FOR DECIMAL MULTIPLES AND SUB-MULTIPLES.

BY R. B. HAYWARD, M.A., F.R.S.

The magnitudes with which the modern physicist and engineer have to deal extend over so wide a range—from millions or billions of some unit to millionths or billionths of the same—that some system of nomenclature for these multiples and sub-multiples—universal, simple, self-interpreting, and with the minimum of arbitrariness—could hardly fail to be a boon for individual use, and still more if generally adopted.

Dr. Houston and Mr. Kennelly have proposed in the *Electrical Engineer* of the 20th inst. a system which satisfies to a certain extent some of the above conditions, but fails in respect of others. It deals with thousandths and millionths, but not with hundredths, ten-thousandths, etc., and the terms are not self-interpreting—*e.g.*, *mega-* and *micro* do not in themselves express 10^6 and 10^{-6} times the unit respectively, but only by a convention, the exact terms of which (I know by experience) those who only need to use them occasionally are liable to forget.

I propose, therefore, to explain a system which I have for some time advocated but not hitherto published in a generally accessible shape, and for which I think I may claim that all the conditions I have laid down above are satisfied. The system is this:

Take any unit, known by its fundamental name (metre, dyne, ohm, etc.), and express by the *affix -n*, *-en*, or *-on* ten times that unit, and by the *affix -t* or *-et* one-tenth of the unit. *Prefix* to these the syllables (of Greek origin) *mono-*, *di-*, *tri*, *tetra-*, etc., to express the *index of the power* of 10 by which the unit is multiplied, the syllable used with the *-n* affix denoting a positive, and that with the *-t* affix a negative index. Thus we obtain the following universal system (exemplified in the case of the metre):

Metres (or other units).	Proposed name.	Name in the metrical system.
10^5 or 100,000	pentametron	?*
10^4 or 10,000	tetrametron	myriametre.
10^3 or 1,000	trimetron	kilometre.
10^2 or 100	dimetron	hectometre.
10^1 or 10	(monometron, or simply) metron	dekametre.
10^0 or 1	Metre	Metre.
10^{-1} or ·1	(monometret, or simply) metret	decimetre.
10^{-2} or ·01	dimetret	centimetre.
10^{-3} or ·001	trimetret	millimetre.
10^{-4} or ·0001	tetrametret	decimillimetre.
10^{-5} or ·00001	pentametret	centimillimetre
10^{-6} or ·000001	hexametret	?*

* The Greeks and Romans have failed to provide us with single words for such high numbers as millions and upwards. At least, our grammars and dictionaries generally stop short at 10,000 or 100,000.

Digitized by Google

The simplicity of the proposed names over those of the metrical system, within, as well as beyond, the limits kilo- and milli-, hardly needs remark. The system has so great an advantage in fixing the attention on the *order* or *place* of a digit (which in using logarithms is the *characteristic*), that I believe it would greatly facilitate the teaching of decimal arithmetic if, instead of the ordinary words ten, hundred, tenth, hundredth, etc., the pupil were taught to use the words *dek*, *didek*, *tridek*, etc., *deket*, *dideket*, *trideket*, etc.; so as, for example, to read the number 5007·0805 as five trideks and seven and eight didekets five tetradekets. Then the product of one tridek and one dideket would readily be seen to be one dek ($3-2=1$), or of eight didekets and five tetradekets = 40 hexadekets ($-2-4=-6$), or the quotient of eight didekets by two trideks to be four pentadekets ($-2-3=-5$).

It will be observed that this system, besides being very simple, is universal in its applicability to any units, that the words interpret themselves without any doubt or hesitation as to their meaning, and that the only arbitrary element is the affix to denote whether a multiple or sub-multiple is to be understood. A few examples will, I believe, conclusively show its advantages.

One foot-pound = $1{\cdot}356 \times 10^7$ ergs, and is therefore in our language 1·356 heptergons.

One horse-power = $7{\cdot}46 \times 10^9$ ergs/sec, and is therefore in our language 7·46 ennergons/sec.

One megadyne, or 10^6 dynes, is one hexadynen.

One micrometre, or 10^{-6} metre, is one hexametret.

Mean distance of the moon = $3{\cdot}844 \times 10^{10}$ centim., read as 3·844 octometrons.

Mean distance of the sun = $1{\cdot}847 \times 10^{13}$ centim., read as 1·847 hendekametrons.

Wave length of D line = $5{\cdot}892 \times 10^{-5}$ centim., read as 5·892 heptametrets.

Number of vibrations per second for D line = $5{\cdot}097 \times 10^{14}$, read as 5·097 × tetrakaidekadekets.*

Energy of heat (J) = 4·2 heptergons per gramme-degree (water).

Dr. Houston's *begohm*, *tregohm*, *quegohm* become in our system *ennohmen*, *dodekohmen*, *pentekaidekohmen* respectively, and his *bicrofarad* becomes *ennafaradet*. If some of these words were felt to be inconveniently long, they might perhaps be shortened by a second *affix* at a certain stage: thus, if a *dekohmen* were called an *ohmenem*, the *dodekohmen* would become a *trinohmenen* and the *pentekaidekohmen* a *hexohmenem*.

PROF. KENNEDY AND ELECTRIC TRACTION.

BY FRANK B. LEA.

Prof. Kennedy has—quite deservedly—obtained a prominent position in the electrical world as an engineer of great skill, experience, and ability, whilst his fairness and impartiality when acting as a consultant stand out rather conspicuously in regard to the average of such qualities. But it is evident that the professor is a mechanical engineer first and an electrical engineer afterwards—if we are to separate the two. The fact of his being president of the Institution of Mechanical Engineers helps partly to explain this, and the address which he gave from the chair before the members of the institution last week may be considered an illustration of it also.

Of course, before such an audience, the professor may have thought it only fair to present in as favourable a light as possible the methods of traction which rely on what may be called purely mechanical principles, and yet the interweaving of electrical with mechanical should have become so intimate that contrasts or comparisons between the main group and the new branch or section would be as impossible as useless. In the case of an electric railway, said the professor, we have truly a saving of weight in the locomotive, but against this advantage, and the fact that a stationary steam-engine can be operated more economically than a steam locomotive, must be set the inefficiency of the whole arrangement. On this point some figures are given which for the professor's sake I will assume were obtained some considerable time ago. One can otherwise hardly credit the statement which he made as to the total efficiency on electrical railways or tramways being no more than 35 per cent., as compared with 80 per cent. on the steam lines. Has Prof. Kennedy analysed the working returns on the Liverpool Overhead Railway, where the ratio between electrical horse-power on the line and indicated horse-power at the station is as much as 88 per cent.? Has he forgotten the fact that on this very line the locomotive has been abolished altogether, the motor mechanism forming part of the passenger rolling-stock in such manner as to have actually no useless weight whatever? Has he, moreover, lost sight of the working results on lines even less favourably situated? Take, for instance, one of the numerous rack railways now at work in the mountainous districts of Switzerland. The Mont Saleve is at present the most important—if not the only one—of these operated by electricity, yet the mean working efficiency, with a most unfavourable arrangement and design of motors and gearing, is not less than 52 per cent. Of the losses, fully 16 per cent. must be set down to the imperfect gearing, so that by improvements in this alone the efficiency on the line would reach nearly 70 per cent.

One is not required in an electrical paper to discuss the economy of steam locomotives, and therefore I say nothing about the 80 per cent. efficiency which Prof. Kennedy—perhaps correctly—claimed for such, except to lay emphasis upon the considerable difference in fuel efficiencies between stationary and locomotive steam-engines. For many reasons he cares not at all for overhead conductors—who would, for that matter, if they had anything better?—and ignores them for the potential perfection of some underground system which has yet to be invented. I doubt very much whether even the late lamented prize of £50,000—or dollars, was it? it makes no difference, however—has succeeded in worrying enough grey brain matter to effect in any way a satisfactory solution of this problem, and to wait until we get one is to lose present advantages on a very large scale. Prof. Kennedy has, it is said, reported at some length and very favourably upon a compressed gas system of operating tramways—a system which is to work the traffic of ordinary lines at a total cost of 1d. per car mile. If this system is the one I have in mind, I feel pretty certain that if it only cost ½d. a mile, or if the tramway company were even paid for the privilege of letting the engines run, they would find it a bad speculation. Ordinary travel is provocative enough of the "railway spine," but to be jerked forward with a regular jerk periodicity of about three seconds would soon empty the cars and ruin the traffic. Moreover, gas and oil engines are all alike in one respect, and that is, their unpleasant qualities as neighbours. They have been said to "bark like a dog and smell like a cat," and the similes are by no means inappropriate.

With the cable system of traction one has no fault to find: it has a distinct field where even electric working may not compete successfully. But for Prof. Kennedy to say that electric traction is being hard pressed by its two rivals, cable and compressed gas, is equivalent to an assertion that the latest infant Hercules finds it a tough fight to turn a couple of harmless snakes out of his cradle. Electric traction must be allowed to exist before it can have any rivals; and for those in prominent positions (who are justly regarded as authorities on such points) to depreciate its possibilities when fairly treated, cannot be said to favour the progress of electricity in this or any other direction.

THE DUNDEE CENTRAL ELECTRIC LIGHT STATION.

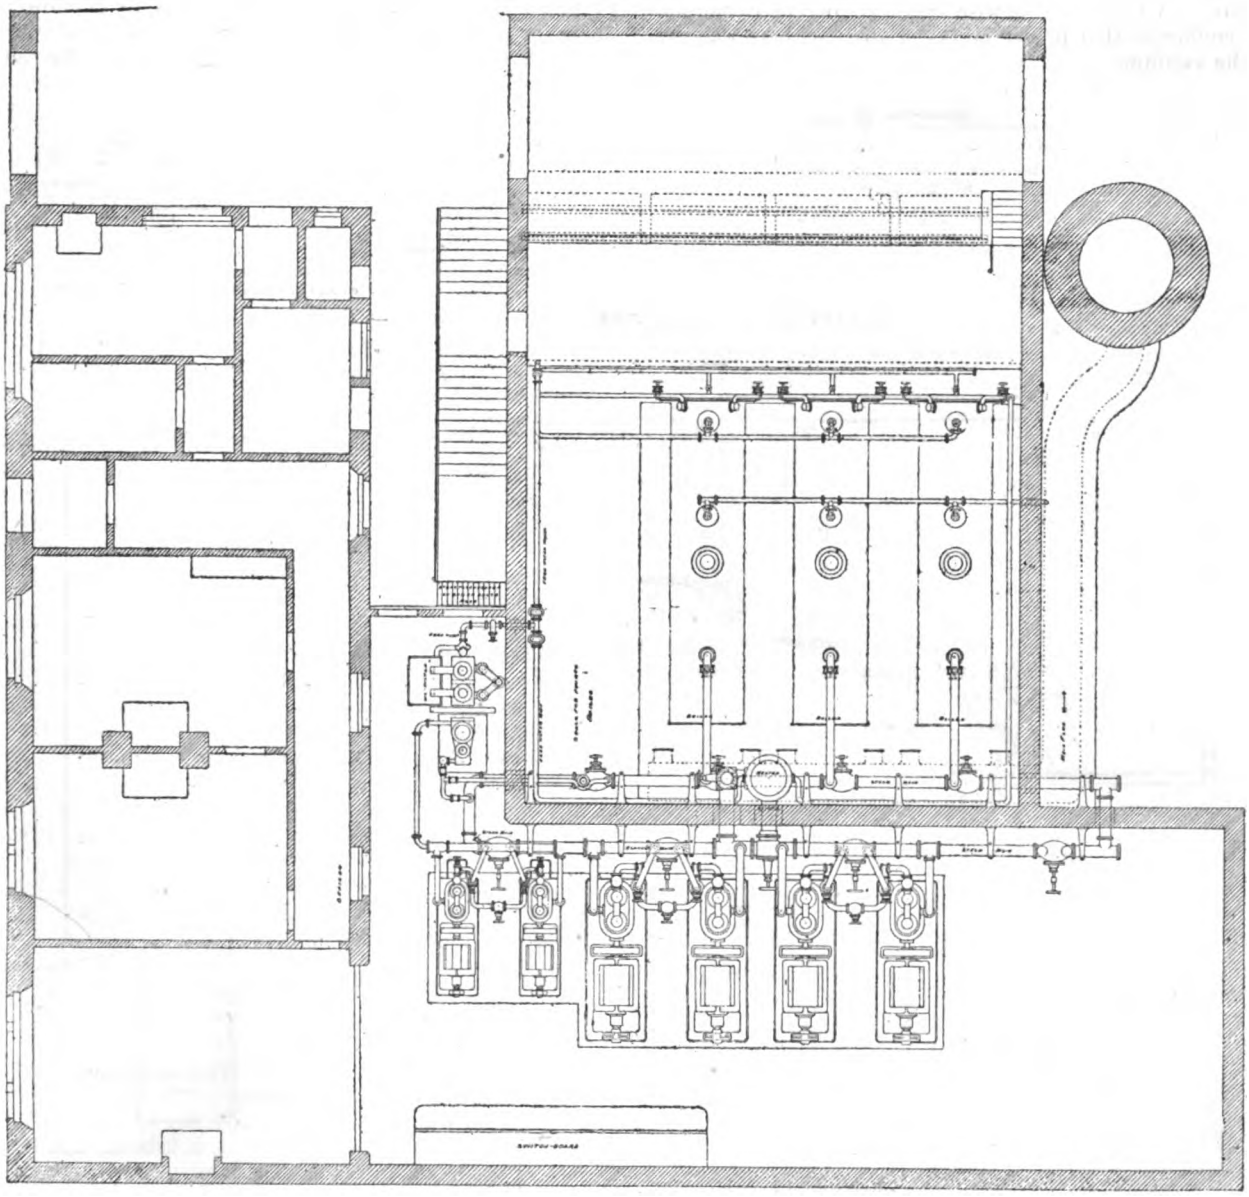
There is a pretty common notion in existence among the inhabitants of England that the adjective of "bonnie" applies to the town of Dundee, whereas it is really a reference to the personal beauty of Graham of Claverhouse, Viscount Dundee. Dundee, the city of jute works, is not remarkable for its picturesqueness, and it looks infinitely better from the opposite shores of the Tay than when one

* The syllable "kai" might, perhaps, be omitted at the expense of linguistic accuracy, but remembering Lord Kelvin's *tetrakaidekahedra*, recently introduced to the public (*Nature*, March 8 and 15), I have not ventured to deviate from his examples.

Digitized by Google

is actually in it. It is split up into business and residential sections, like most other towns; but many of its manufacturers choose to take up their abode at Broughty Ferry, a little nearer to the mouth of the river. It was, of course, to be expected that the inhabitants of a town of the importance of Dundee, which takes the third place in Scotland, would require the electric light; and their demands were met on March 15, 1893, when a public supply of electricity was commenced from a central station which faces the Dudhope-crescent-road.

The supply has been undertaken by the Dundee Gas Commissioners, and the available ground space at the generating station is sufficient to allow of extensions being made for a total of 20,000 16-c.p. lamps, or about three times the present capacity. The station is centrally situated between the business and residential parts of the city, and the method introduced is the three-wire system, the nominal pressure between the outside conductors being 200 volts.



Dundee Electric Light Station. FIG. 1.—General Plan of Station and Offices.

As will be seen from the accompanying illustrations, the buildings comprise a one-storey block, consisting of boiler and engine house, instrument, testing, and engineers' rooms, clerk's office, porter's lodge, storerooms, etc., and a basement accommodating a battery of accumulators. The general arrangement of the station is shown in plan in Fig. 1.

The steam-generating plant comprises three boilers of the Lancashire type, constructed for a working pressure of 140lb. There is, however, space for the accommodation of a fourth boiler. Each boiler is 24ft. long and 7ft. in diameter, and has two flues 2ft. 6in. in diameter. Provision has been made for equipping the boilers at any time with mechanical stokers. With regard to the feed water, special precautions have been adopted so as to prevent a failure in the supply. For this purpose each boiler is connected to two mains, one being fed by an injector and the other by a pump driven by an air-pump engine. Besides this, the two mains are again cross connected and fitted with valves in such a manner that either pump or injector can supply either or all the boilers through either of the mains. There is also provided a feed-water heater, heated by the exhaust from the steam-engines, and, if desired, the feed water from either of these mains can be passed through it. The arrangements adopted for the fourth boiler allow of its being connected to the steam and feed mains.

It will be seen from Fig. 1 that the steam-mains have been constructed in the form of a closed ring, divided into sections by means of stop-valves. A branch pipe is led to an engine from each side of a valve. This arrangement is amplified by the connection of the two branches—one on each side of a stop-valve—with one another again by a steam-pipe. This by-pass is joined into the branch pipes between the engine stop-valve, and another valve on the branch pipe. In the case of repairs being necessary on the main, this arrangement permits of the cutting out of a section by closing the valves. At the same time the engines connected to this section can still be supplied with steam from the pipe leading to the adjoining engine whether the engine is running or at rest. The steam-mains are made of wrought iron, the internal diameter being 8in. and the thickness ¼in. The flanges are also of wrought iron, screwed and brazed on, whilst the bends and T-pieces are of cast iron. The method adopted to avoid an unnecessary number of joints has been to cast the

Digitized by Google

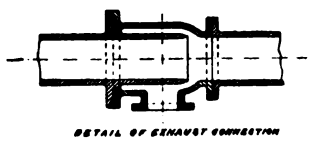
flanges, where the branches to the engine join on to the steam-main, in one with the valve bodies. The main is drained by three steam-traps. The main, being in the form of a closed ring, has not necessitated the use of expansion joints, more particularly as the branch pipes leading to the engines are of copper, and are sufficiently long to allow for expansion.

Similarly to the steam-main, the exhaust is also made of wrought iron, and it ranges from 5in. to 12in. in diameter, according to the amount of steam exhausting into it. Where the exhaust joins the main, it is constructed somewhat in the form of an injector. Thus the exhaust, instead of causing a back pressure, which would occur if carried in at right angles to the main, has a tendency to produce a vacuum behind it, and so assists in reducing the back pressure. Valves are likewise arranged on the exhaust of each engine, so that it may be taken apart without destroying the vacuum.

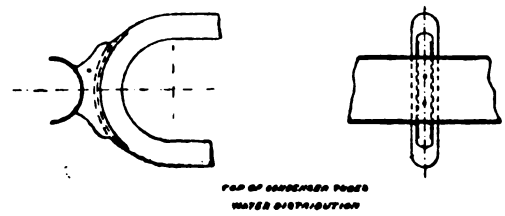
boiler-house, upon which six flat tanks are placed, of which four only are at present used.

There are four exhaust pipes above the tanks, and these communicate with the exhaust main. From the horizontal pipes there rise vertically 192 ∩ tubes. One leg of each ∩ connects with the horizontal pipes, while the second leg is joined to a smaller pipe, which runs parallel to the larger pipes. These smaller pipes and the air-pump are connected. The steam is thus obliged to ascend one leg of the ∩ and come down the other. The air-pumps draw off the condensed steam from the two horizontal pipes situated above each tank. The arrangement is illustrated in Fig. 3.

A gutter, supported on cast-iron feet, runs above each of the rows of ∩ tubes, the feet resting on the top of the ∩ tubes. The flat tanks already referred to contain the water for condensing purposes. A belt from the air-pump engine drives a centrifugal pump, which draws the water

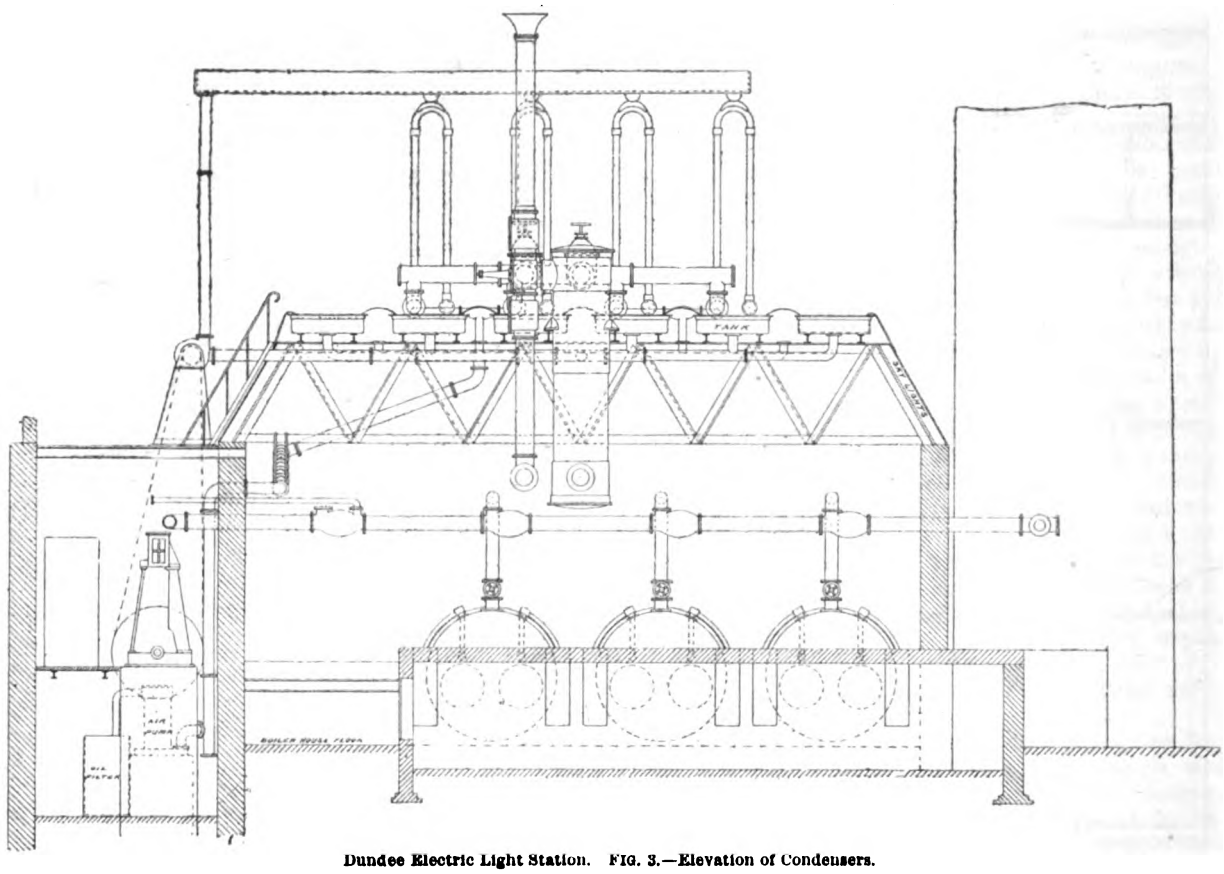


DETAIL OF EXHAUST CONNECTION



TOP OF CONDENSER TUBES
WATER DISTRIBUTION

ELEVATION OF CONDENSERS



Dundee Electric Light Station. FIG. 3.—Elevation of Condensers.

The engines, which have been supplied by Messrs. Willans and Robinson, are six in number—four being H H and two G G. Space is, however, provided for the laying down of two additional engines when necessary. The engines are of the compound type, and can be used either condensing or non-condensing; they are erected on a large block of concrete, 10ft. thick, and only let into the ground a depth of 2ft. Two T branches at the centre of the exhaust main pass on to the boiler-house through the wall. Of these, one is next carried up through the roof, while the other is led to the feed-water heater. The two exhausts are then again joined, there being a valve fixed at the connection, which has been so designed that should the condenser fail and cause the rising in the heater of the back pressure, the steam would escape direct to the air. A tubular heater, hung from the boiler-house roof, is employed. Warren girders have been employed in the construction of the roof of the

from the tanks and delivers it into the gutters on the top of the ∩ tubes. Two small holes are made in the gutter over each ∩. The water escapes through the holes, and runs down on to the outside of the ∩'s, the brackets supporting the gutter distributing it over the surface.

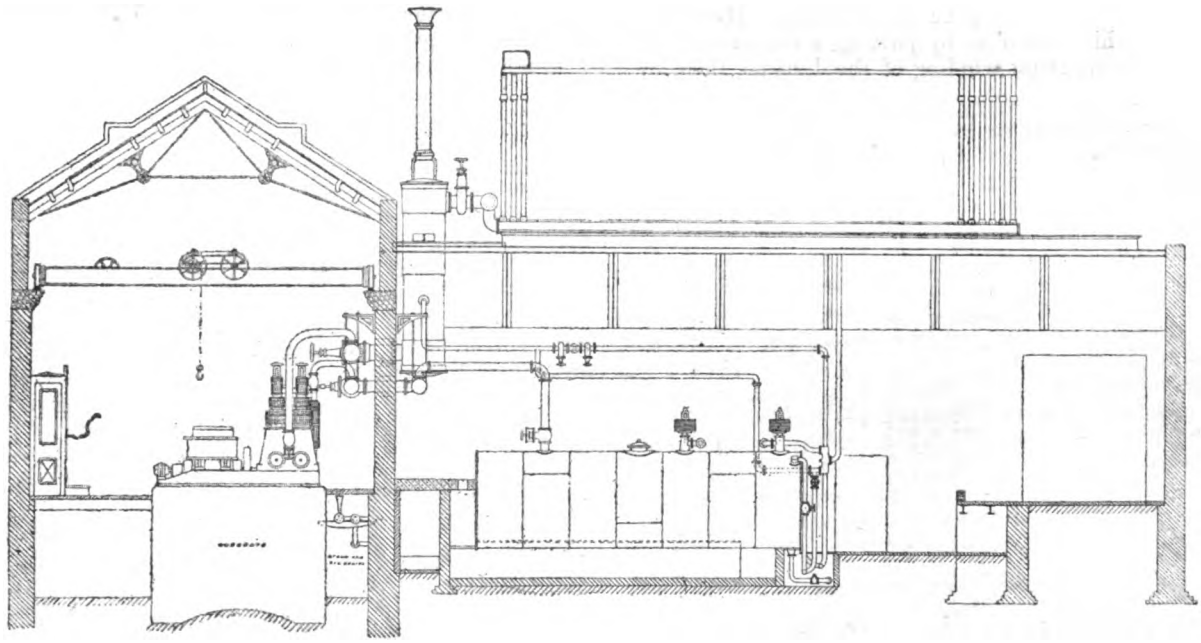
As already stated, there are two spare tanks on the roof. These have been provided in view of future extensions. At present the condenser has a capacity for dealing with steam from engines of 540 i.h.p., more than double the existing capacity of the station.

A vertical compound engine, with 7in. and 13½in. cylinders, drives the air-pumps. Messrs. Whyte and Cooper, of Dundee, made the engine, the condensing plant, and the steam-mains. There are two air-pumps, of 18in. diameter and 12in. stroke. The engine and pumps are coupled direct. All the water before being returned to the boiler is filtered to get rid of oil.

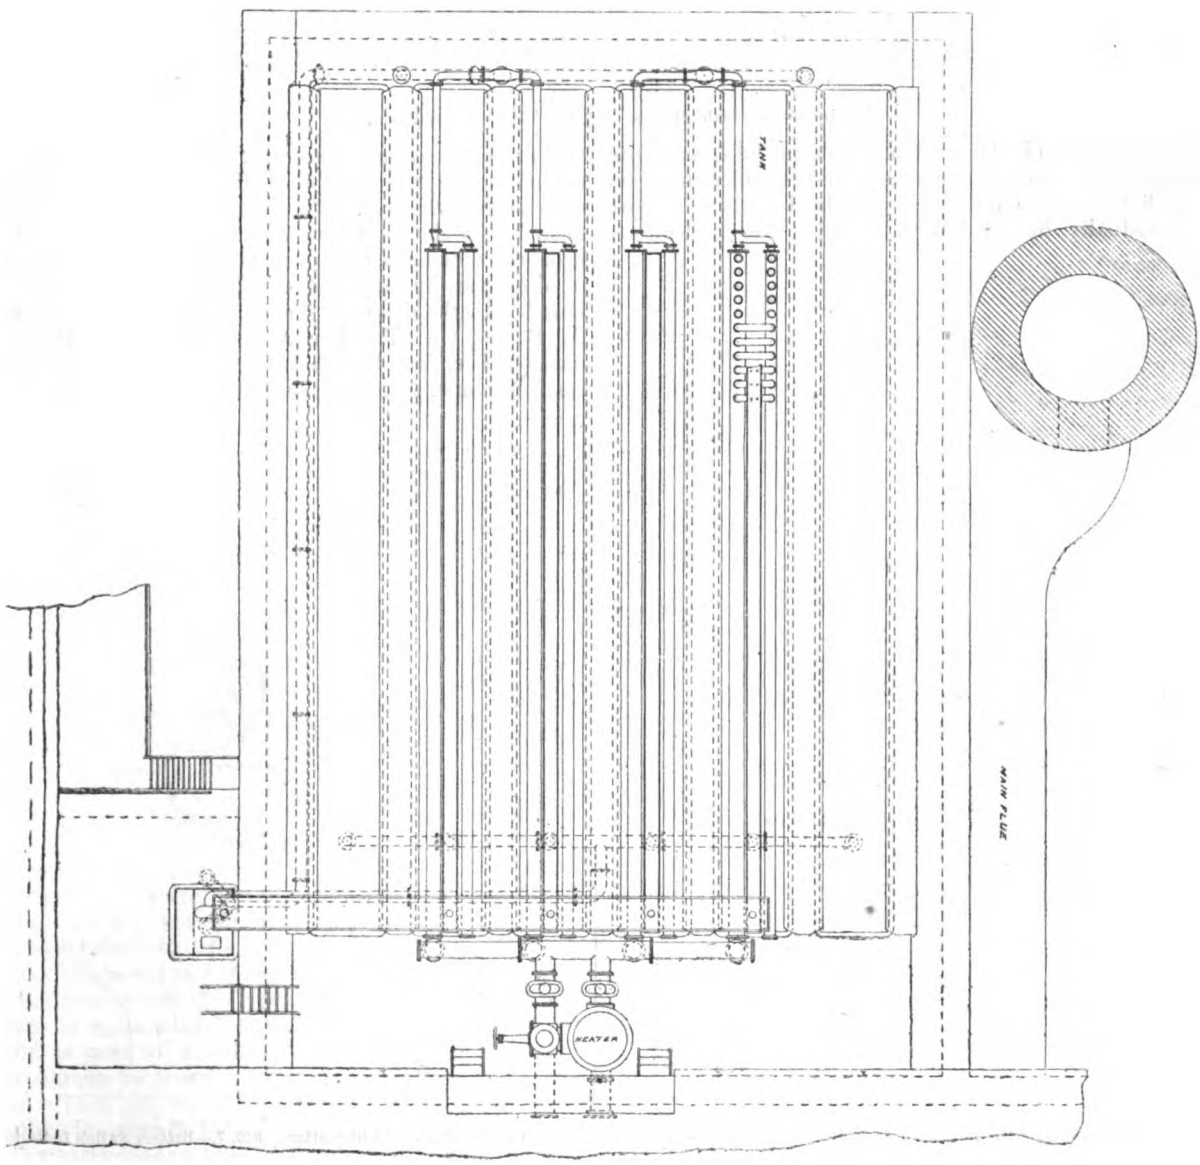
The dynamos have been made by Messrs Siemens

Digitized by Google

Bros. Four of them are H.B. $^{18}/_{36}$ and two H.B. $^{15}/_{23}$. They are coupled direct to the Willans engines. The machines, at their normal speed of 360 revolutions per minute, give 250 volts, the smaller machines at a normal



Dundee Electric Light Station. FIG. 2.—Cross-section of Engine and Dynamo Room and Boiler House.



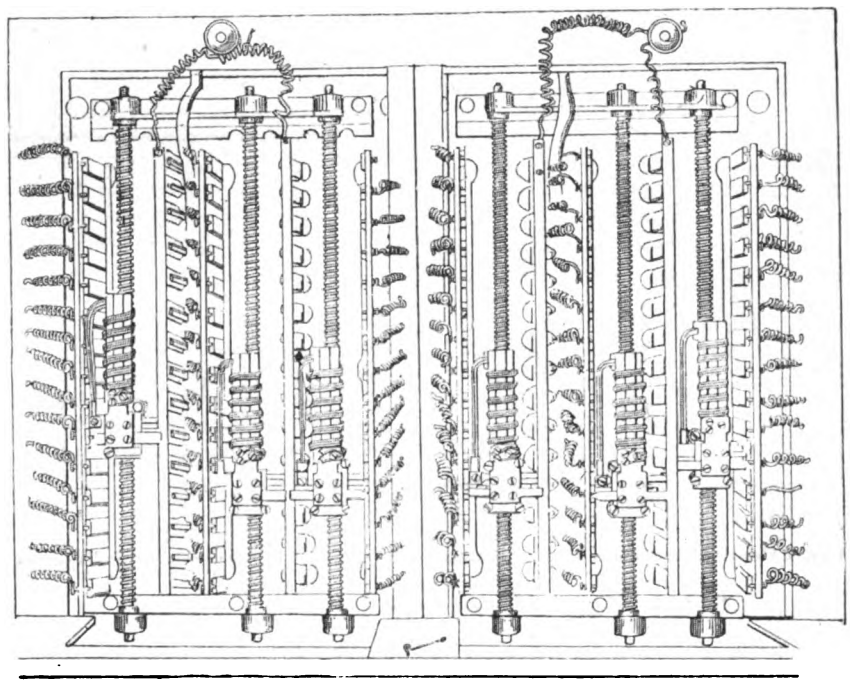
PLAN OF CONDENSERS

Dundee Electric Light Station. FIG. 4.—Plan of Condensers.

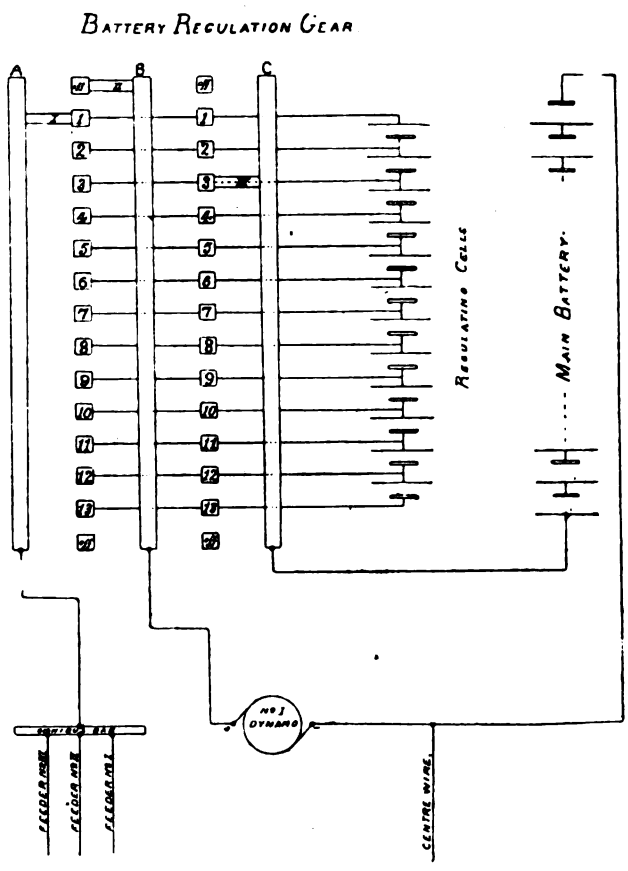
machines are shunt wound. The four large dynamos have each an output of 87,500 watts. The two smaller machines have each an output of 43,400 watts. The larger speed of 450 revolutions give 140 volts. The shunt of each dynamo is provided with a variable resistance for varying the volts on the machines from 200 to 250 in the

Digitized by Google

larger machines, and from 100 to 140 in the smaller machines. They are also provided with a Siemens shunt-breaking resistance to avoid breaking down the insulation through suddenly opening the shunt circuit. How this is avoided in this switch is by putting a resistance first in parallel with the shunt winding of the dynamo, then, by a further movement of the switch, breaking the connection with the exciting circuit. This puts the resistance in series with the field coils, round which the field current surges until it gradually dies out. With regard to the connections on the switchboard, the four larger machines supply direct to the outside mains, while the two smaller ones and the batteries are used for balancing.

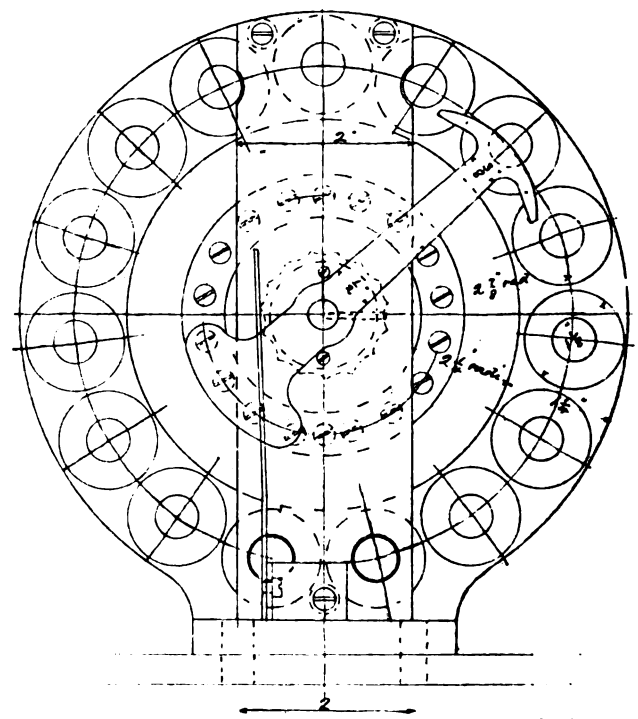


Dundee Electric Light Station. FIG. 6.—Regulating Battery Switch.



Dundee Electric Light Station. FIG. 5.—Battery Regulation Gear.

What is believed to be a new and original method of regulating on the mains, whether the current is being supplied from or to the battery or direct from the dynamos, has been introduced. The regulating cells are entirely detached from the main battery. In order to more clearly explain the principle of this method, we show diagrammatically in Fig. 5 the regulating gear for the positive battery. It will be observed that a switch is provided, consisting of three contact bars with two rows of contacts between them. Each contact is connected to the cells, and two "off" contacts are arranged at each end of the row. The two rows of contacts are connected with the three long contact bars by means of three brushes, which can be moved independently of one another or altogether by means of suitable gearing on the switchboard. In the diagram the long contact bars are marked A, B, and C. The bar A is connected to the positive omnibus bar, bar B direct to the positive terminal of a small dynamo, and bar C to the positive pole of the main battery. The negative pole of the dynamo and battery are connected to the central wire. Dealing with the action of this switch, we will consider that all the brushes are on No. 1 contact, and that the resistance of the two circuits is the same, the counter E.M.F. of the battery being here regarded as a resistance. It



Dundee Electric Light Station. FIG. 7.—Battery Switch Indicator.

Digitized by Google

will in this case be obvious that half of the current supplied by the dynamo will pass to the omnibus bar, and half go to the main battery. If now, for the purpose of charging the main battery it is required to raise the E.M.F. on C, and yet A is still required to be kept constant, by lowering brush I. to contact 2, two volts are put in as a counter E.M.F. on the town circuit; the volts on the dynamo must then be raised by altering its shunt, or the volts may be raised before moving the switch. Thus, by lowering brush I. the volts on the battery circuit can be raised to any extent without altering the volts on A. When the battery is fully charged, any more current can be prevented from flowing into it by moving the brush back towards I. and lowering the volts on the dynamo until the volts on dynamo and battery are alike. In this case the dynamo and battery are supplying A in parallel; or it can be done another way—viz., by lowering brushes II. and III. together, at the same time lowering the volts on the dynamo as before. If now it is required to supply the omnibus bar from the battery, the dynamo being shut down, by lowering brush III. until it is on or below I. the battery will be feeding on to the omnibus bar. It will be seen that when brush III. is below I. the regulating cells are in series with and adding their E.M.F. to that of the main battery; and when brush I. is below III. they are in series, but adding a counter E.M.F. It will also be evident that by moving all three brushes together no change in the electrical conditions take place, but that fresh cells are brought into use. One great advantage of this arrangement is that instead of, as in the usual arrangement, only the end cells being used, any of them can be used, and, when required, the charged cells can be used to supply current with the main battery or dynamo, and the discharged cells used where a counter E.M.F. is required in charging, and so a considerable economy can be effected. The regulating battery switch by which these effects are produced has been constructed by Messrs. Johnson and Phillips. It consists of seven enamelled slates, each 6ft. by 3ft. 3in, mounted on a wrought-iron frame. A perspective view of the same is given in Fig. 6. At present there are six feeders, three + and three −, but provision has been made, though at present the instruments are not fixed, for putting in six more. The instruments connected to the two regulating dynamos and the batteries are fixed on the centre slates, the instruments connected with the larger dynamos, and also the distributing bars, being mounted on the outside ones. The voltmeters are of Lord Kelvin's electrostatic type, and the ammeters are by Messrs. Hartmann and Braun. Meters are provided on the batteries, which indicate the current supplied to them, and which deducts the current supplied from them. The gearing for controlling the before-mentioned battery regulating switches, which are fixed on the wall of the battery-room in the basement, is fixed on the board and connected to the switch by shafting and bevel gear.

It is very essential that a brush of the switch should not be left touching two contacts at the same time, as by so doing they would short-circuit a cell. To prevent this happening, indicating gear, shown in Fig. 7, is fixed on the back of the board. It consists of as many small magnets as there are contacts on the switch mounted in a circle. Each magnet is excited by the brush on the switch closing a local circuit. In the centre of each circle of magnets an armature is fixed, to which is connected a pointer which goes through the board to a dial on the front. The attendant on moving the battery switch by the hand-wheel on the board, sees by the movement of the pointer which contact the brush is resting on. The object of indicating the position of the brush electrically is that as the battery switch is some considerable distance from the board, it would be next to impossible to make sure of the position of the brush by trusting to the mechanical gearing, as any wear or back lash would introduce uncertainty as to whether the brushes were in their proper positions or not.

The batteries are the E.P.S. type, and each consists of 48 K-46 cells in glass boxes. The regulating batteries contain 12 cells each, and hospital cells have been provided.

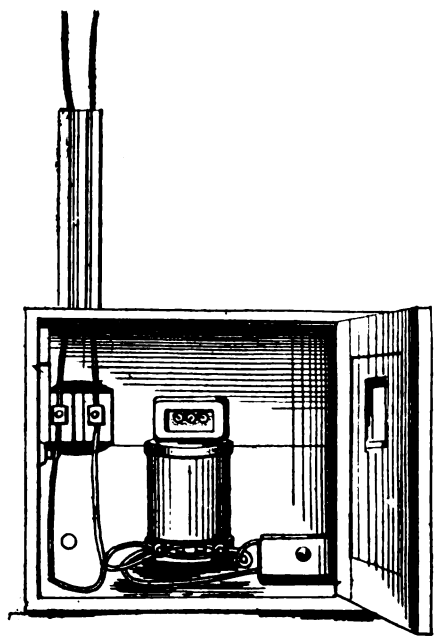
The distributing mains are of vulcanised indiarubber cable, and were supplied by the India Rubber, Gutta Percha, and Telegraph Works Company, Limited. They are laid in wrought-iron pipes under the pavements. All the house connections are vulcanised. The feeders were supplied by the Callenders Bitumen Company, and are of bare copper laid in concrete culverts, great care having been taken to thoroughly drain them.

Under the boiler-house roof has been fixed an artificial resistance capable of absorbing 100,000 watts. It is divided up into sections by a switch for varying the load on it, and is used for testing the dynamos, and to provide an artificial load when the load on the town is very small. Continual records, on self-recording instruments by Richard Frères, are taken of the volts and amperes on the feeders, the volts being taken both at the station and at the point where the feeders join the distributing network. Kelvin standard instruments have also been provided for testing and calibrating the other instruments and for testing meters.

It may be mentioned that the station has been running continuously since it was started on March 15, 1893, and the current sold up to December 31 last reached 66,238 units. Since then a large number of additional lamps has been connected to the mains. We must not omit to state that Messrs. Urquhart and Small, of 17, Victoria-street, S.W., were the consulting engineers for the Dundee Gas Commission in the carrying out of this station, and we are indebted to them for the accompanying illustrations.

A METER-BOX ARRANGEMENT ADOPTED BY THE CORPORATION OF HULL.

There are several reasons, not to mention conveniences, why it is advisable to thoroughly protect electricity supply meters which are fixed on the premises of a consumer, and which are intended to register the amount of supply. What these reasons are it is neither necessary nor wise to explain, and for the purposes of this description they may be considered as already admitted. Every manager of an electricity supply company will very readily appreciate the advantages to be gained by the arrangement which is shown in the accompanying illustration. He



will doubtless understand the advisability of keeping an intelligent public from that little knowledge of electricity which is apt to be a very dangerous thing as far as the interests of the supply company are concerned. Moreover, reasons for protection also apply to the consumers' terminals and to the company's main fuse, and on the low-tension system, which is the system at Hull, it has been found convenient to place these fittings, together with the meter, in one case. The illustrations show the case open. When closed, the record can easily be read through a small glass window in the door.

Digitized by Google

The case is sealed up with a wire and a lead seal. In this arrangement no part of the main cables is exposed, and the casing containing them may also be sealed if desired. The idea of this combination originated with Mr. James Piggott, who is the outdoor superintendent and meter inspector of the Electric Lighting Committee of the Hull Corporation.

INSTITUTION OF MECHANICAL ENGINEERS.

ADDRESS BY THE PRESIDENT, PROF. ALEXANDER B. W. KENNEDY, LL.D., F.R.S.

It is a well-known difference between engineering practice in this country and in most others that the conditions of our work seldom allow us to carry specialisation to any such great extent as is common, for instance, all over the Continent. With us the belief that a man is "a thorough practical engineer"—whatever that may mean—is very generally taken as evidence that it is safe to ask him to do anything whatever which may be included within the vague general term "engineering." Of the extent to which this feeling is carried, as well as—I must say—of the essential truth which lies at the bottom of it, no better illustration could possibly be found than the position now held, with so much advantage to the public service, by my distinguished predecessor in this chair, Dr. Anderson. Some of us have occasion to examine continually the epitomised professional histories of engineers who wish to belong to, or to be promoted in, our institutions. It is quite noteworthy in how many cases, especially in our own institution, a man of thirty-five or forty is found to be working with great success in a line totally different from that in which he gained his first experience.

The existence in the minds of the public, who are, in fact, our employers, of the feeling which I have mentioned, no doubt brings us very often into temptation—temptation to undertake work or responsibility in directions where our own common sense only, unaided by past experience, must be our guide. He is a wise man who can tell, as each opportunity presents itself, whether it is really a tide to be taken at its flood, or whether it is one in which his swimming powers will not be sufficient to carry him on to fortune, but may only leave him, and those who trust to him, still short of *terra firma* when the ebb commences. The consideration of this point has probably caused many of us more anxious moments than the actual working out of any of the knotty engineering problems which come upon us after the plunge is taken. I speak in the matter from hard enough experience, for I myself have had all too often to decide such questions, sometimes in one sense and sometimes in the other. So it happens, that having served my time with marine engineers, I have had in the last 25 years to busy myself with half-a-dozen varieties of mechanical and structural work (including what I may call the academic variety during many happy years at University College), and, of late years, also with the newest variety of all—electrical engineering. I trust that my electrical friends—those of them, that is, who are 20 years younger than I am—will forgive me for calling electrical engineering a variety of mechanical work. I mean nothing disrespectful, of course; but even to those who are much more thoroughly electrical engineers than I can ever hope to be, but who have the chronological misfortune, like myself, to have become engineers before technical electricity existed (if I may be allowed so to speak), I think it must always be so To such of us, electrical work has been grafted on to mechanical; and any success we have had in the one, we trace back to its foundation in our knowledge of the other. And further—although I know that in this I lay myself easily open to an accusation of mere conservatism—I believe that even now the only really safe road to success in electrical work lies through the old routine of mechanical training, modified, of course, by the excellent means for studying the scientific side of the work which now exist in so many directions.

It is common on occasions like the present for the speaker to lay before the members such matters out of his own personal knowledge or research or experience as he thinks may be most generally useful to them, as some small acknowledgment of the honour which he has received at their hands in his election as their president for the year. In thinking how best I could fulfil this honourable obligation and pleasant duty it occurred to me, in connection with the train of thought which I have just put before you, that as I happen by some chance to be the first of your presidents who has been actively connected with electrical work, it might be of interest to you, and possibly also of use to some, if I endeavoured to put before you as clearly as I could the way in which the electrical problem of to-day in this country presents itself when looked at from the mechanical engineer's point of view rather than from the electrician's—in other words, from your point of view and mine.

Practical electrical problems divide themselves probably into three main sections, in which electrical energy is used respectively for (1) lighting; (2) power; (3) physico-chemical processes. The third section—where energy is used for the deposition of metals, for the reduction of chemical compounds, etc.—falls outside my own knowledge. From what I know of the success with which it is being worked, I cannot doubt that it has a great future. But its problems only touch engineering very indirectly as yet, and therefore hardly come within the subject which I have prescribed to myself. In this section may be included, at least for present purposes, the application of electricity to heating. So many active and competent workers are at present engaged on this matter that it is greatly to be hoped that success may soon atend their work. Not only the difficulty of producing the heat, but also that of producing it in a convenient fashion, have been overcome to a very large extent. The remaining difficulty is the purely commercial one of producing the heat sufficiently cheaply to allow of its general use. This, I am afraid, has not yet been overcome; and until it has been, electrical heating unfortunately hardly comes within our ken except for very special purposes. Remembering that something like 95 per cent. of all the energy that goes to incandescent lamps appears only as heat, and not as light, there appears to be an ample opening here for another "thermal storage" process, at least, until the present lamps are superseded by the less wasteful type which the future will doubtless reveal to us in good time

The use of electrical energy for power—*i.e.*, for transformation into mechanical energy—is a matter which lies obviously in the closest possible connection with mechanical engineering. It divides itself broadly into three sections—viz., (1) transmission from a distance for whatever purpose; (2) transmission to a number of isolated points comparatively near together, as the tools in a factory; and (3) transmission for the purposes of traction on railways or tramways. The transmission comes in in every case because we have as yet no electric prime mover analogous to a steam-engine. The electric motor presupposes the existence of a dynamo, which must itself be driven by some prime mover. From the dynamo to the motor, whether near or far apart, there must always be transmission of electrical energy. In a recent extraordinary aberration it seems to have been discovered that there was some positive advantage in using steam-engine. dynamo, and motor all in one place to do work hitherto done by the steam-engine alone. This wonderful locomotive. however, forms, and no doubt will continue to form, a class by itself! As to the transmission of power from a distance I shall not say anything, mainly because I could say nothing so well as it has quite lately been said by Prof. Unwin in his Howard lectures. The whole matter is there discussed with so unusual a combination of impartiality, scientific accuracy, and mechanical common sense as to make the lectures, short as they are, into one of the most important contributions to engineering literature which have appeared in this country for a very long time. In particular, one cannot help being struck with the judicial way in which the author has kept clear of the fatal fascination which this matter possesses over many minds otherwise sane—a fascination which in some cases goes so far that one finds the whole matter discussed, perhaps unconsciously, on the basis that it is a positive advantage to transmit power from the longest possible distance! There are several towns in the United Kingdom where the use of water power for the purpose of electric lighting will have some day to be seriously considered, but I hardly think that beyond these the present generation is likely to see any great development in this direction at home. In other parts of the world the conditions are, of course, very different, and English engineers who wish to secure their share of work in this direction will rather have to study it beyond the limits of their own country.

The question of driving the tools in a factory by electric motors instead of through countershafting is one which has recently come to the front. The carrying out of such work is obviously purely a matter of mechanical engineering. Its advisability in any particular case is partly a question of economy and partly one of convenience, and is undoubtedly dependent on the conditions of each particular case. I have found from information very kindly given me by several large engineering firms, that the actual cost to them of power, including coal, stores, wages, and depreciation, generally lies between 2 and 5 per cent. of their total costs. In any given factory running on the ordinary system there is a large continuous waste of power due to the running of the whole shafting, no matter how many or how few machines are at work. Under such conditions the waste work in shafts and belts may well be even 25 per cent. of the average useful work, and the distribution of total work may be approximately:

	H.P.
Average useful work	100
Wasted in belts and shafting	25
Wasted in engine friction, the engine being supposed large enough to give 150 h.p. at tools as a maximum (at about 10 per cent. of maximum horse-power)	20
	145

Now, if all the machines in such a case were driven by separate motors, each having an electrical efficiency of 88 per cent., and these motors worked from a dynamo having an efficiency of 92 per cent. (both of which are high figures for ordinary work at two-thirds output), the figures would stand as folllows:

	H.P.
Average useful work	100
Wasted in motors and dynamo	24
Wasted in leads (say 2 per cent.)	2
Wasted in engine friction (as above)	20
	146

It will be seen that the two sets of figures are practically the same as to amount of power required. As the electrical efficiencies which I have assumed are not likely to be exceeded, I think it may be said that there is no saving to be obtained in horse-power, and none, therefore, in any of the items of cost directly dependent on horse-power, in cases where the power wasted in shafting and belts does not exceed 25 per cent. of the whole average useful

Digitized by Google

power. This is a ratio which any engineer can most readily obtain for himself if he is not afflicted with that sense of the insuperable difficulty of making any simple and exact experiment which still remains one of the obscure diseases of our profession. I have no no doubt cases can be found where the waste in large factories with very widely distributed power is very much greater than the proportion assumed, and in such cases no doubt a saving in power costs would occur.

But at the root of the matter there probably lies one ultimate determining point, far too often neglected in such calculations as I have just been making. This point is, of course, the real absolute saving to be made as distinguished from the proportionate saving. It is of little use to show an engineer that he can make even 20 per cent. saving in some one item of expenditure if that whole item only represents 3 or 4 per cent. of his costs, and if at the same time he has to expend a considerable amount of capital in making the change. One does not make important and expensive changes, especially changes whose result is by no means very certainly to be predicted, to bring about an estimated saving of ½ or 1 per cent. in one's total expenditure. I fear that this is a matter which may prove a more serious difficulty in the way of the success of the great Niagara scheme than any of those described by Prof. Forbes. In reference to our present point, it will prove sufficient to prevent the adoption of isolated motors in engineer's works in all cases except where the waste in belt and shaft transmission is exceptionally great, or where for other reasons electrical driving *per se* is desirable. For the whole matter is certainly not concluded either one way or the other by this single consideration. There can be no doubt, on the one hand, of the practical convenience of getting rid of the huge mass of shafting, gearing, and belting which fills up the upper half of many engineers' shops, although it is difficult to fix any money value for this advantage. There is no doubt also that a properly-arranged motor may give a much larger range of speed to each tool than can be readily obtained in the ordinary way, and will thus enable more and better work to be got out of it, with skilful management. Were it not that such magnificent work has often been turned out in this country from such dirty and apparently disorderly shops, I should also say that it was self-evident that every change which improved the general orderliness and tidiness of the shop must—reacting upon the men employed—improve the output both in quantity and quality. Under the actual circumstances one hesitates to be dogmatic on this point, but I incline to believe that it is true, and that the good work to which I have referred has been turned out in despite of its environment, and has been due to exceptional excellence in workmen or managers or both, and that with the same men it might even have been still better under better working conditions. On the other hand, it has to be pointed out that the cost of dynamo, leads, and motors is very greatly indeed in excess of the cost of shafting in almost every case. It is also hardly certain as yet how the costs of attendance, lubrication, renewals, and repairs to the electrical plant compare with the similar costs in the case of shafts and belting. Probably on the whole they would be less, but no satisfactory data on this point exist.

There arise two special cases which should be mentioned. In cases where electrical energy can be obtained from public mains the comparison is quite different. The working of the printing machines, for instance, in the office of the *Pall Mall Gazette* is carried out electrically, the current being derived from the mains of the Charing Cross and Strand Electric Supply Company. The works in this case get rid of all costs of engines and boilers, with all their many inconveniences, and also gain in space most of the room occupied by their old plant. Moreover, they have a better security against breakdown than they could otherwise very well afford to have without most costly duplication of plant. The matter then becomes simply one in which increased space, convenience, and security are to be balanced against increased cost, and each case has to be considered on its own merits. At present it is not very certain how the engineer supplying the electric energy ought to look at such a case. His chief business is, and will be, to supply energy for lighting purposes. As is sufficiently well known, the demand for lighting energy varies enormously throughout the 24 hours, so that, in fact, a plant which is giving 2,500 h.p. for a couple of hours every day, and which, of course, must be large enough for this purpose, leaving still machines in reserve, will only be giving an average of 350 h.p. taken over the whole week, and not even half this for many hours every day and night. It is, of course, very desirable to increase the load during the hours of light load, and if this could only be done without also increasing its present maximum—that is, without necessitating increase of plant—engineers could afford to sell the additional energy at a very low rate indeed. Unfortunately, the condition I have mentioned is impossible. There will always come hours when, through fog or other special causes, the power load will coincide in time with the lighting load. And even if this were to happen only once or twice a year, the engineer must none the less provide plant for it and keep the plant ready. The case is not met by differential charges at different hours. The plant must be provided all the same, and the additional outlay will not be met by the extra payment for a few hours' work per annum. It may, however, very well be met by the value of the additional work done on 360 days out of 365, at times when otherwise nothing would be done. This point I shall deal with later on.

A second special case occurs when the cost of power forms a very large, instead of a very small, proportion of the whole running costs of the works, and no doubt in several industries this is the case to a very much greater extent than in engineering works. I will ask you particularly to notice that in the case where electrical driving supersedes belts, the work is not done any less directly than before. Between the engine and the tool there stand, in the one case belts and pulleys and shafts twice or thrice repeated, and in the other case dynamo and leads and motor, with or without a small belt from motor or machine. It is quite possible that the actual mechanical efficiency of the belts is greater than that of the two electrical machines and the leads between them. But in the case of the shafts and belts the losses are continually going on whether or not useful work is being done, whereas there are no losses in the motors unless they are actually running and driving tools. This brings the total losses equal in the case I have supposed, and in other cases may make the electrical method more economical. But the change is merely a substitution of one indirect method for another equally indirect method.

In the third great case of electric transmission of power, for the purpose, namely, of driving trains or tramcars, we have a state of affairs which is entirely different, and which, I am afraid, is by no means so favourable to the use of electricity as is sometimes supposed. In the case of a train drawn by an engine in the usual way, we have the whole of the net power of the engine, exclusive of that spent in internal friction and in actually hauling itself along—say 80 per cent. of the gross indicated horse-power—available for pulling its load along the line. In the case of an electric railway we have truly a somewhat lighter locomotive to be moved, but against this advantage and the fact that a stationary engine can have a greater economy than a locomotive, we have the uncomfortable state of affairs that only some 35 per cent. of the whole indicated horse-power, as against 80 per cent., is available for the useful work of pulling the train. It seems, moreover, hardly likely that this low percentage will be much increased. The cause of the loss is, of course, the extreme indirectness of the process—that is, the very great number of transformations through which the energy has to pass, in each of which there is always a loss. We may take the figures approximately somewhat thus, always remembering that the average power would be less, probably very much less, than three-quarters of the full power of the plant at work :

	Per cent.
Mechanical efficiency of engine	85
Efficiency of belt driving (if employed)	94
Efficiency of dynamo	90
Efficiency of line	85
Efficiency of motors	85
Efficiency of gearing on locomotives	75
Total efficiency, per cent.	39

From this is to be deducted, say, 10 per cent. for driving the locomotive, leaving 35 per cent. for pulling the train. I think it may fairly be said that to a mechanical engineer the greatest enemy to all economy is frequency of transformation, and that it is, or ought to be, a fundamental rule in all engineering work that every unnecessary transformation, whether mechanical or electrical, should be avoided. Notwithstanding this terrible drawback, the absence of foul gases is of such overwhelmingly great importance in some cases that the working of the City and South London line has only been possible at all because electricity has been employed instead of steam. This, of course, is a case where mere economy of power was not the only or even the most essential thing sought for. In the Liverpool Overhead Railway, also, the conditions of the case rendered the use of steam locomotives impossible, as the line runs along a route on which they are prohibited. The case of tram lines along streets differs altogether from that of an underground or indeed any other railway. Here the steam-engine with its boiler is a bulky and objectionable affair, very apt to cause smoke and other disagreeables, and very unsuitable for trains which consist of one vehicle only, weighing less than its locomotive would have to weigh. I have often wondered why the Serpollet boiler and engine have not been introduced for tram work. They take so little space that they might very possibly be put on the car itself (the car being made reversible as at Manchester), but I suppose some difficulties have been found ; at any rate the proposal has not been made, so far as I know. But apart from this, and not forgetting the steam cars which are actually at work in certain places in the North, there is probably no form of steam car which would be generally endured by the public. Here, again, therefore, electricity would appear to come in regardless of cost, in the same way as with the underground railway, although for another reason. But here we are met at once with the mechanical difficulty (not existing, of course, in the tunnel or on the overhead railway) of getting the current to the motors on the car. In America the knot is cut, rather than untied, by the use of overhead wires, and in country places it is probable that this may be here the best solution of the problem. But in our cities, where the bulk of the tramway traffic of the country is really carried on, I am still conservative enough to think, and also to hope, that this is impossible. Without forgetting the much-quoted case of Budapest, therefore, I fear that the introduction of electricity for car-driving in this country will still wait until a practicable underground system has been devised. Meanwhile it is being hard pressed by its rivals—cable and compressed gas. Of the two I think the latter, although the younger, is far the more formidable. It has the advantage of being even more direct than a steam-engine (the boiler being absent) ; it can be applied to each individual car even more easily than an electrical motor, and it enables the car to run freely on ordinary lines without their reconstruction, and without any mains either above or below ground. It has as yet had but short trial, but what I have seen of it makes me sanguine as to its ultimate possibilities.

Before speaking more particularly about the mechanical aspect of electric lighting problems, I feel bound to touch upon a matter

Digitized by Google

which arises directly out of the question of supplying electric energy for power and for light concurrently, to which I have just drawn attention. It is a favourite bit of cheap criticism indulged in by those who have not to supply energy on a large scale at the expense of those who have, that the former class of folk show their ignorance of their own work and interests by neglecting to obtain that enormous demand for motive power which would come on them if only they reduced their prices low enough. The criticism is really as absurd as that other which censures the gas companies because they do not supply heating gas at a few pence per thousand feet, which apparently they would be perfectly able to do if only they knew their own business half as well as their critics do! In both cases the criticism is mere words, "signifying nothing." We have simply to remember the fact that the mere possibility of driving something by electricity does not of itself create the things that want to be driven. There are isolated districts in London—Clerkenwell, for instance, and the neighbourhood of Fleet-street—in which there is a considerable amount of power of a kind which might be furnished electrically if the cost were made sufficiently low. In most parts, however, the whole energy expended in doing mechanical work is but a very small percentage indeed of the energy required for light, and it would not be increased in the least even if it were supplied for nothing. When the inhabitants of Mayfair and Kensington, for instance—to take these districts only as typical of many others—take to brushing their boots, washing their faces, and serving their meals by electricity, a demand will have arisen which may perhaps be fostered into something worth considering. Until this happy state of affairs comes about, I fear that the demand for motive power in English residential and semi-residential districts must remain a factor practically negligible in the calculations of the engineer. Whether in a purely manufacturing district it may ever be found to pay to put down a central power station and transmit power to factories, each of which would replace its steam-engine and boiler by an electric motor, is a question about which there is a good deal to be said on both sides. I have already indicated the lines along which I believe this matter will settle itself.

I pass now to the last and largest section of my subject, the question of public electric lighting from the point of view of the mechanical engineer. From the side of the public—that is, of the users of electric light—the essential points are simple—viz., that the light should not visibly flicker, that it should not be below the declared pressure nor very much above it, that it should be available at all hours, and, of course, most of all, that it should never go out. But any notions one might have that in consequence of the simplicity of this final result the means of attaining it would also be simple, are very speedily dispelled by a consideration of the facts. It is, alas! not sufficient to provide a shed, a boiler, a decently-governed engine, and a dynamo and alternator, and many and sad have been the disappointments in consequence. The fact is that although the final result to be attained is always the same, and is always extremely simple and straightforward, the conditions under which that result has to be obtained are always varying, and are not only extremely complex in any one place, but are also different altogether in each different place. To members of this institution, however, I need not point out that this is not any cause for grumbling—the more difficult and complicated the problem, the more chance there is for the engineer in working out its solution. I will consider first those variations which are entirely beyond the control of the engineer—*i.e.*, the variations of load—and afterwards those which are within his power—*i.e.*, variations in the working of the station. To those of you who have practically to do with these matters the variations I have to speak of are absurdly familiar, but to others—probably the majority—they are still sufficiently unfamiliar to be of some little interest. I have therefore prepared diagrams which may illustrate them.

Diagram 1 shows the variations of output of a lighting station during a whole year. Each vertical division stands for one week. Irregularities are due to particularly foggy weeks, or to weeks in which public holidays occur, such as Easter and Whitsuntide. For the rest the curve follows pretty obviously the changes in daylight, except that the minimum occurs not in the very middle of the summer, but during August, in consequence of the large number of private houses which are shut up at that time, while the days are still too long to require the use of any artificial light in shops which close at 7 o'clock. Diagram 2 shows the variations within a week, each vertical division standing for one day. Here, of course, the chief variation is that which occurs on Saturday and Sunday. Diagram 3 shows the variations occurring within one day, the vertical divisions each standing for one hour. In this diagram three days are actually shown, one in December, one in August, and one in June, and it will be noticed that the three are very different. In winter there is practically always a double maximum, one occurring about breakfast time or in the forenoon, after which the load falls off in the middle of the day and reaches its full maximum towards evening. In the summer time the morning load disappears altogether, and there is only one maximum, which occurs much later than it does in winter. In fact I have noticed that in London, at any rate, the average time up to which people use light is fully an hour later in the summer than it is in the winter, a somewhat interesting fact in sociology. In August the "peak" of the diagram becomes a minimum, the private houses using no light because they are closed, the shops because the days are still too long. The red line on Diagram 1 shows in rather an interesting fashion that the maximum load and the maximum output by no means vary together. The maximum load is much more constant than the maximum output, and does not vary nearly so fast or so much. The quantity which chiefly varies is the time during which that load lasts, and this time is, of course, dependent on the hours of sunlight, or more particularly on the interval between sunset and closing or bedtime.

Besides the variations shown in these diagrams it is right that I should mention one or two others. A very important class of variations are those which may be said to be due to latitude. In a place as far north as Aberdeen, for instance, there is practically no night for two months in the year, and for a much longer time than this no lighting whatever is used in shops, and hardly any in private houses. On the other hand, the hours of lighting in the winter are proportionately longer than in the South. The effect upon the annual output diagram would be not to alter its area considerably, but to thicken it up in the winter and reduce it very much in the summer. As an illustration of northern loads I have shown in Diagram 4 load curves for a winter and a summer day, taken at a little station which was running in Glasgow supplying offices some two years ago. One set of variations which puzzles and troubles the engineer very much is the varying amount of light thought necessary by people in different parts of the country. No doubt this depends to a considerable extent upon the nature of the premises in which the light is used, but even this is hardly sufficient to explain the whole of it. In a purely residential district in London, for instance, the average energy used per annum is only about 12 units per lamp wired. In a mixed district, like that of the Westminster Company, it is about 16 units per lamp wired. In a very rich district containing many clubs, like that of the St. James's Company, one is not surprised to find that it amounts to 22 units per lamp wired. But one is on the whole surprised to find that in Newcastle it should be as much as 25 units, and in Leeds 27. It is no doubt with less surprise that one notices that the consumption of 38 units per lamp which existed in Exeter when current was paid for by contract, and not by meter, was exactly halved as soon as consumers were made to pay for the amount which they really used.
